Proceedings of the 12th International Conference on Educational Data Mining
Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds).
July 2nd – 5th 2019 Montréal Canada
ISBN: 978-1-7336736-0-0

PREFACE

For this 12th iteration of the International Conference on Educational Data Mining (EDM 2019), the conference returned to its birthplace in Montreal, Quebec, Canada. EDM is organized under the auspices of the International Educational Data Mining Society in Montreal, Canada. The conference, held July 2nd through 5th, 2019, follows eleven previous editions (Buffalo 2018, Wuhan 2017, Raleigh 2016, Madrid 2015, London 2014, Memphis 2013, Chania 2012, Eindhoven 2011, Pittsburgh 2010, Cordoba, 2009 and Montreal 2008).

The theme of this year's conference is EDM in Open-Ended Domains. As EDM has matured it has increasingly been applied to open-ended and ill-defined tasks such as writing, design, and collaborative problem solving. And it has been used in new informal contexts where student actions are at best semi-structured. This iteration of the conference includes a range of work in these and other areas. This year's conference features three invited talks: Julita Vassileva, Professor at the Department of Computer Science, University of Saskatchewan, Canada; Steve Ritter, Co-Founder and Chief Scientist, Carnegie Learning Inc., Pittsburgh, USA; and Michael Mozer, Professor Department of Computer Science and Institute of Cognitive Science University of Colorado, USA.

This year's EDM conference has adopted a double-blind review process. Further, the program committee has been substantially extended, both to better reflect the community presenting works at EDM in the past years and to keep the review load for each member manageable. The number of papers submitted in the research track has increased compared to preceding years, resulting in 185 long and short paper submissions from 32 countries. Of these, 22 were accepted as full papers and 42 accepted as short papers. The combined acceptance rate of long and short papers is 34.6%. The acceptance rate for long papers is 21%. An additional 47 papers were accepted to the poster track. The poster and demo track itself accepted 14 contributions out of 34 submissions.

Together with the Journal of Educational Data Mining (JEDM), the EDM 2019 conference held a JEDM Track that provides researchers a venue to deliver more substantial mature work than is possible in a conference proceeding and to present their work to a live audience. The papers submitted to this track followed the JEDM peer review process. Seven papers were submitted and two papers are featured in the conference's program. Additionally this year, papers that were regularly published in the journal in 2018 were invited for presentation at the conference. Two authors accepted this invitation.

The main conference invited contributions to an Industry Track in addition to the main track. The EDM 2019 Industry Track received eleven submissions of which six were accepted. These figures are comparable, though slightly increasing, with last year's figures and suggest that connections between industry researchers and the academic research community become firmer.

The EDM conference continues its tradition of providing opportunities for young researchers to present their work and receive feedback from their peers and senior researchers. The doctoral consortium this year features eight such presentations.

Finally, stepping in the footsteps of last year's conference, this year's conference includes also an invited talk by the authors of the 2018 winner of the EDM Test of Time Award. This year's talk is delivered by Mykola Pechenizkiy.

In addition to the main program, there are three workshops: Learning Analytics: Building bridges between the Education and the Computing communities, Reinforcement Learning for Educational Data Mining, and Workshop on EDM & Games: Leveling Up Engaged Learning with Data-Rich Analytics, and three tutorials as well: Sharing and Reusing Data and Analytic Methods with LearnSphere, Causal Discovery with Tetrad in LearnSphere’s Tigris and Designing and Developing Open, Pedagogically-Based Predictive Models using the Moodle Analytics API.

We thank the sponsors of EDM 2019 for their generous support: Tourism Montréal, Prodigy, Ivado, SAS, Squirrel AI Learning, and ACT as well as our two host institutions: Université du Québec à Montréal (UQAM) and Polytechnique Montréal. We are also thankful to the senior program committee and regular program committee members and reviewers, without whose expert input this conference would not be possible. Finally, we thank the entire organizing team and all authors who submitted their work to EDM 2019. And we thank EasyChair for their infrastructural support.

<i>Collin F. Lynch</i>	North Carolina State University,	Program Chair
<i>Agathe Merceron</i>	Beuth University of Applied Sciences Berlin,	Program Chair
<i>Michel Desmarais</i>	Polytechnique Montréal,	General Chair
<i>Roger Nkambou</i>	Université du Québec à Montréal,	General Chair

July 2nd, 2019
Montreal, QC, Canada.

ORGANIZING COMMITTEE

General chairs: Michel Desmarais (Polytechnique Montréal) and Roger Nkambou (Université du Québec à Montréal)

Program chairs: Collin F. Lynch (North Carolina State University) and Agathe Merceron (Beuth University of Applied Sciences Berlin)

Workshop & Tutorial Chairs: Luc Paquette (The University of Illinois at Urbana-Champaign) and Cristobol Romero (University of Cordoba)

Industry Track Chairs: KP Thai (Yixue Education) and Mary Jean Blink (TutorGen)

Doctoral Consortium Chairs: Andrew Lan (Princeton University) and Mykola Pechenizkiy (Eindhoven University of Technology, TU/e)

JEDM Track Chairs: Michael Yudelson (ACT, Inc.) and Andrew Olney (University of Memphis)

Poster & Demo Track Chairs: Bruno Emond (National Research Council of Canada) and Jill-Jenn Vie (RIKEN, Tokyo)

Sponsorship Chairs: Steven Fancsali (Carnegie Learning, Inc., Pittsburgh) and Roger Nkambou (Université du Québec à Montréal)

Volunteer Chairs: Sophie Calliès and Ange Tato (Université du Québec à Montréal)

Publicity/Social Media Chair: Michael Eagle (Carnegie-Mellon University)

Web chair: Paul Salvador Inventado (California State University, Fullerton).

IEDMS Officers:

Mykola Pechenizkiy,	President	Eindhoven University of Technology, Netherlands
Kenneth Koedinger,	President-elect	Carnegie Mellon University, USA
Mingyu Feng,	Treasurer	WestEd, USA

IEDMS Board of Directors:

Rakesh Agrawal	Data Insights Laboratories, USA
Ryan Baker	University of Pennsylvania, USA
Tiffany Barnes	North Carolina State University, USA
Michel Desmarais	Ecole Polytechnique de Montreal, Canada
Sidney D'Mello	University of Colorado Boulder, USA
Luc Paquette	University of Illinois Urbana-Champaign, USA
John Stamper	Carnegie Mellon University, USA
Kalina Yacef	University of Sydney, Australia

Program Committee

Lalitha Agnihotri	McGraw Hill Education
Rakesh Agrawal	Data Insights Laboratories
Esma Aimeur	University of Montreal
Bitu Akram	North Carolina State University
Giora Alexandron	Weizmann Institute of Science
Boyer Anne	Kiwi Team - LORIA
Mirjam Augstein	Upper Austria University of Applied Sciences, Communication and Knowledge Media
Roger Azevedo	University of Central Florida
Costin Badica	University of Craiova, Computer and Information Technology Department, Romania
Ryan Baker	University of Pennsylvania
Richard Baraniuk	Rice University
Tiffany Barnes	North Carolina State University
Nabil Belacel	National Research Council
Suma Bhat	University of Illinois at Urbana-Champaign
Gautam Biswas	Vanderbilt University
Mary Jean Blink	TutorGen, Inc.
Nigel Bosch	University of Illinois Urbana-Champaign
Jesus G. Boticario	UNED
François Bouchet	Sorbonne Université - LIP6
Alex Bowers	Columbia University
Kristy Elizabeth Boyer	University of Florida
Javier Bravo Agapito	Madrid Open University (UDIMA)
Keith Brawner	United States Army Research Laboratory
Christopher Brinton	Princeton University
Armelle Brun	LORIA - Université Nancy 2
Peter Brusilovsky	University of Pittsburgh
Zhiqiang Cai	The University of Memphis
Renza Campagni	Università degli Studi di Firenze
Alberto Cano	Virginia Commonwealth University
Ted Carmichael	TutorGen, Inc.
Zhongzhou Chen	University of Central Florida Physics Department
Min Chi	North Carolina State University
Mihaela Cocea	School of Computing, University of Portsmouth
Scott Crossley	Georgia State University
Cynthia D'Angelo	University of Illinois at Urbana-Champaign
Sidney D'Mello	University of Colorado Boulder
Michel Desmarais	Ecole Polytechnique de Montreal
Prasenjit Dey	IBM
Shayan Doroudi	Carnegie Mellon University
Kerrie Douglas	Purdue University
Guillaume Durand	National Research Council Canada
Michael Eagle	Carnegie Mellon University
Asmaa Elbadrawy	Arizona State University

Bruno Emond	National Research Council Canada
Collin F. Lynch	North Carolina State University

Amelia Zafra Gómez	Department of Computer Sciences and Numerical Analysis
Alfredo Zapata González	Universidad Autonoma de Yucatan
Diego Zapata-Rivera	Educational Testing Service
Chengxiang Zhai	University of Illinois at Urbana-Champaign
Guojing Zhou	North Carolina State University
Craig Zilles	University of Illinois at Urbana-Champaign
Amal Zouaq	Polytechnique

SPONSORS

Best Paper Selection

The conference chairs selected the three best papers based upon the reviews and meta-reviews for each paper. The papers were then sent to an outside awards committee. Each committee member read and ranked the three papers. The best paper award was attributed to the highest ranked paper. The best student paper was awarded to the next highest ranked paper in the set.

Best Paper Award Committee

- Rakesh Agrawal
- Ryan Baker
- Andrew Olney
- Luc Paquette
- Kalina Yacef

Best Paper Nominees

Benoît Choffin, Fabrice Popineau, Yolaine Bourda and Jill-Jänn Vie. *DAS3H: a new student learning and forgetting model for optimally scheduling distributed practice of skills* page 39.

Markel Sanz Ausin, Hamoon Azizsoltani, Tiffany Barnes and Min Chi. *Leveraging Deep Reinforcement Learning for Pedagogical Policy Induction in an Intelligent Tutoring System* page 178.

Ye Mao, Rui Zhi, Farzaneh Khoshnevisan, Thomas Price, Tiffany Barnes and Min Chi. *One minute is enough: Early Prediction of Student Success and Event-level Difficulty during Novice Programming Tasks* page 129.

TABLE OF CONTENTS

Keynotes

On the Ethics of Data-Powered Instruction, Recommendation, Persuasion, and Behaviour Change.....	1
--	---

Julita Vassileva

Reconsidering two sigma: Educational data mining for the complete instructional system.....	3
---	---

Steve Ritter

Educating a synthetic student	4
-------------------------------------	---

Michael Mozer

JEDM Presentations

Predictiveness of Prior Failures is Improved by Incorporating Trial Duration	5
--	---

Luke G. Eglington and Philip I. Pavlik Jr.

Will this Course Increase or Decrease Your GPA? Towards Grade-aware Course Recommendation	6
---	---

Sara Morsy and George Karypis

The Continuous Hint Factory - Providing Hints in Vast and Sparsely Populated Edit Distance Spaces	7
---	---

Benjamin Paaßen, Barbara Hammer, Thomas Price, Tiffany Barnes, Sebastian Gross and Niels Pinkwart

Using Sequence Mining to Analyze Metacognitive Monitoring and Scientific Inquiry based on Levels of Efficiency and Emotions during Game-Based Learning.....	8

On the Ethics of Data-Powered Instruction, Recommendation, Persuasion, and Behaviour Change

Keynote

Julita Vassileva
Department of Computer Science
University of Saskatchewan
Saskatoon, Canada
jiv@cs.usask.ca

Abstract

Advances in information technology and miniaturization, along with falling prices, allow affordable and powerful computing devices and sensors to become ubiquitous. These devices, equipped with advanced software and learning technologies resulting from 40 years of research in the areas of AI in education and cognitive modeling, can transform the way people learn and truly democratize education. Technological learning tools also generate valuable data about human learning processes and interactions. Through learning analytics and data mining, predictive models can be built enabling tailored or personalized support for individual learners and groups. For example, recent advances in reinforcement learning or partially observable Markov decision processes combined with semantic domain and pedagogical knowledge representations enable the design of optimized subject curriculums as well as flexible individualized learning and evaluation sequences. Progress in data mining including new fast algorithms for tensor decomposition enable recommending educational content appropriate to the learner's context, goals, knowledge, cultural background, personality, and motivational and affective states.

In parallel with developments in AI and Cognitive Psychology, research focus in the areas of Artificial Intelligence in Education (AIED) and Educational Data Mining (EDM) has broadened to address affective and social aspects of learning, as well as increasing the motivation of learners and engaging them in productive behaviours. Persuasive technologies, based on methods and strategies developed by neuroscientists, social psychologists and behavioural economists have shown effectiveness in engaging people in the desired behaviours.

This keynote talk focuses on the potential of persuasive technologies for supporting human learning. Many researchers in the AIED and EDM communities may not be aware of this potential. Persuasive technologies can make a bigger difference than gaining a fraction of percentage point on the RMSE of predicting the success rate over the next recommended item (a common debate on the value of accuracy of student skills modeling). Similarly, persuasive visualizations of individual or group student models facilitates processes of reflection, social learning, social comparison and competition, which have been shown to motivate learners and engage them in learning activities.

In my vision for the not-too-distant future personalized intelligent educational and persuasive technologies converge to support lifelong learning as people adapt to the rapidly changing natural and social environment. People will learn not only curriculum-based knowledge, but also knowledge on demand to achieve important goals like preserving the environment and enhancing civil society. Technologies of this scope face ethical challenges, related to their fairness and trustworthiness, power-balance, and the need to sustain the mental-health of people increasingly interacting exclusively with and through technology. Research attention in the Machine Learning (ML), Recommender Systems (RecSys), and Artificial Intelligence (AI) communities has already zoomed in on the ethical issues of the technologies they develop, specifically on the fairness, accountability and transparency (FAT) of data-driven systems, but understandably seeking mostly algorithmic solutions. Persuasive technology can provide methods for increasing the transparency of algorithms and correspondingly, the user trust in systems' data-driven decisions. Yet many of the problems with fairness and accountability are not algorithmic, but come from the complex, messy,

Julita Vassileva "On the Ethics of Data-Powered Instruction, Recommendation, Persuasion, and Behaviour Change" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 1 - 2

and inconsistent data fed to the algorithms. Bias in the ways data is collected, managed, annotated and used combined with lacking legal frameworks can lead to poor decisions, discrimination, violating the privacy of individuals, and exposing them to manipulation, which can have detrimental effects on society.

Data-hungry algorithms require big data, which leads to data hoarding. This generates multi-billion dollar businesses, and creates a great asymmetry in power between individuals, societies, or states and data-harvesting companies. Big data is opaque due to limited human cognitive processing power and attention span; full transparency seems intractable. A lot more research is needed to enable environments that offer equally good services, but are not so data-hungry, environments using small data, collected and used in context and then forgotten, managed by enforceable contracts with the users who can also gain rewards from sharing their data.

Personalized and persuasive social media applications has been blamed for being addictive by exploiting dopamine reward loops in the brain. We notice increased frequency of mental health issues, such as anxiety, depression, manias, addictions in young people but still we plan to engage them even more with our systems, reinforcing these problems. Maybe our systems should be teaching them how to detach from the technology, how to change their behaviours to engage with the real world and in real relationships, to meditate and find peace in the frenzy of information?

The keynote talk will address some of these issues and how persuasive technology, interactive visualization, and distributed ledgers can be used to provide solutions. It will also touch on research that isn't yet happening, but is needed, for example, enhancing learners' awareness of the dangers of personalization technology through personalized persuasive technology.

Bio

Dr. Julita Vassileva is a professor at the University of Saskatchewan and a leading researcher in user modelling, personalization and social computing, as well as AI in Education. She has authored over 250 research papers in the areas of intelligent tutoring and recommender systems, user modeling and personalization, trust and reputation, persuasion and behavior change. She is a member of the editorial boards of several reputed journals, including User Modeling and User Adapted Interaction, IEEE Transactions of Learning Technologies, ACM Transactions on Social Computing, International Journal of AI in Education and is the founding Editor-in-Chief of Frontiers in AI section on AI Supporting Human Learning and Behaviour Change. Dr. Vassileva was elected in 2017 to the Board of CS-Can |Info-Can (the Canadian Computer Science Society), and serves as a Chair of the Research Committee of the Board. Over her 20 years on faculty, she has advised over 35 graduate students (10 PhD and 27 MSc) and was nominated by her students and received the two main awards of the University of Saskatchewan for graduate supervision: the University's Distinguished Graduate Supervisor Award (2014), and the Advising Excellence Award by the Graduate Student Association (2013). Dr. Vassileva held the NSERC/Cameco Chair for Women in Science and Engineering for the Prairies region (2005 – 2011) and started a science outreach program for aboriginal youth in the North, called "Science Ambassadors", which has now completed 12 years of impactful activity in over 25 communities and has engaged over 25,000 indigenous youth in science. For her leadership and mentorship she was awarded the Saskatoon's YWCA "Women of Distinction Award (Science and Research)" in 2015.

Reconsidering two sigma: Educational data mining for the complete instructional system

Keynote

Steve Ritter
Carnegie Learning
Pittsburgh, Pennsylvania, USA
sritter@carnegielearning.com

Abstract

Educational software developers have long focused on achieving Bloom's (1984) goal of producing software that is as effective as a personal human tutor. Much progress has been made and, by some measures, this goal has been achieved (van Lehn, 2011). But maybe this is the wrong goal. The *two sigma* problem sets up a competition between teacher-based instruction and educational software. In the classrooms where Carnegie Learning's MATHia software is most used, there is no need to pick a winner. Most student usage of the software is in the presence of a teacher, and students can benefit from both. A better goal than improving on the teacher's instruction, then, may be to think of the teacher and the software as cooperating instructional resources with differing characteristics.

This perspective on the goal of educational software can lead to better design decisions focused on improving the overall educational experience for the student. Instead of attempting to reduce the teacher's classroom role, we focus on focusing the teacher on opportunities to have the biggest impact. During class, the software and the teacher communicate insights about student abilities and needs, enabling each to do a better job. In this talk I will illustrate ways that we use data to provide teachers with insights that help them assist students using MATHia. The teacher, in turn, provides MATHia with information that enables the software to perform better. While this is a new perspective for us, we are starting to see how this systems approach has led to even stronger educational outcomes for students.

Bio

Steve Ritter is Founder and Chief Scientist at Carnegie Learning. He has been developing and evaluating educational systems for over 20 years. He earned his Ph.D. in Cognitive Psychology at Carnegie Mellon University and helped start Carnegie Learning to ensure that the successful Cognitive Tutor approach was available to students across the country. Carnegie Learning's blended mathematics curricula, including MATHia software (formerly called Cognitive Tutor) are currently used by over 500,000 students each year.

Dr. Ritter was instrumental in the development and evaluation of the Cognitive Tutors for mathematics. He is the author of numerous papers on the design, architecture and evaluation of Intelligent Tutoring Systems and other advanced educational technology and is recognized as an expert on the design and evaluation of educational technology and on educational analytics. He is lead author of an evaluation that is one of the few to be judged by the US Department of Education's What Works Clearinghouse as meeting their standards without reservations. He has received several awards, including the Best Paper award at the International Conference on Educational Data Mining.

Dr. Ritter leads Carnegie Learning's research group, which is charged with focusing on improving student outcomes through data mining and field experimentation.

Educating a synthetic student

Keynote

Michael C. Mozer
University of Colorado at Boulder
and Google Brain
Boulder, Colorado, U.S.A.
mozer@colorado.edu

Abstract

In educational data mining, we use behavioral data to better understand learners and the nature of learning. I hope you agree with this characterization because it says nothing about whether the learner is a biological or a synthetic agent. In this talk, I focus on deep neural networks as learners. Modern nets have become so complex that we need to use experimental and modeling tools to characterize their behavior, just as we do for humans. Such analyses support the design of robust AI agents, but they also help to identify human-surrogate models that can be used to optimize instructional methods for people.

Bio

Michael Mozer received a Ph.D. in Cognitive Science at the University of California at San Diego in 1987. Following a postdoctoral fellowship with Geoffrey Hinton at the University of Toronto, he joined the faculty at the University of Colorado at Boulder and is presently a Professor in the Department of Computer Science and the Institute of Cognitive Science, as well as a Visiting Faculty Researcher at Google Brain (Mountain View). He is secretary of the Neural Information Processing Systems (NeurIPS) Foundation, has served as Program Chair and General Chair at NeurIPS and as chair of the Cognitive Science Society. He is interested in human-centric artificial intelligence, which involves designing machine learning methods that leverage insights from human cognition, and building software tools to optimize human performance using machine learning methods.

Predictiveness of Prior Failures is Improved by Incorporating Trial Duration.

Luke G. Eglington

Philip I. Pavlik Jr
Institute for Intelligent Systems
University of Memphis
ppavlik@umemphis.edu

Abstract

In recent years, there has been a proliferation of adaptive learner models that seek to predict student correctness. Improvements on earlier models have shown that separate predictors for prior successes, failures, and recent performance further improve fit while remaining interpretable. However, students that engage in "gaming" or other off-task behaviors may reduce the predictiveness of learner models that treat counts of prior performance equivalently across gaming and non-gaming student populations. The present research evaluated how sub-groups of students that varied in their potential gaming behavior were differently fit by a logistic learner model, and whether any observed differences between sub-groups could inspire the creation of new predictors that might improve model fit. Student data extracted from a college-level online learning application were clustered according to speed and accuracy using Gaussian mixture modelling. Distinct clusters were found, with similar cluster patterns detected in three separate datasets. Subsequently, each cluster was separately fit to a Performance Factors Analysis model (PFA). Significantly different parameter coefficients across clusters implied that students more likely to have been gaming benefitted less from prior failures. These differences inspired new and modified predictors that were found to improve overall model fit - an improvement that varied in magnitude across clusters. The present findings indicate that incorporating trial duration into counts of prior failures can improve the predictive power of learning models.

Abstract

In order to help undergraduate students towards successfully completing their degrees, developing tools that can assist students during the course selection process is a significant task in the education domain. The optimal set of courses for each student should include courses that help him/her graduate in a timely fashion and for which he/she is well-prepared for so as to get a good grade in. To this end, we propose two different *grade-aware course recommendation* approaches to recommend to each student his/her optimal set of courses. The first approach ranks the courses by using an objective function that differentiates between courses that are expected to increase or decrease a student's GPA. The second approach combines the grades predicted by grade prediction methods with the rankings produced by course recommendation methods to improve the final course rankings. To obtain the course rankings in both approaches, we adapt two widely-used representation learning techniques to learn the optimal temporal ordering between courses. Our experiments on a large dataset obtained from the University of Minnesota that includes students from 23 different majors show that the grade-aware course recommendation methods can do better on recommending more courses in which the students are expected to perform well and recommending fewer courses in which they are expected not to perform well in than grade-unaware course recommendation methods.

Abstract

Intelligent tutoring systems can support students in solving multi-step tasks by providing hints regarding what to do next. However, engineering such next-step hints manually or via an expert model becomes infeasible if the space of possible states is too large. Therefore, several approaches have emerged to infer next-step hints automatically, relying on past students' data. In particular, the Hint Factory (Barnes and Stamper, 2008) recommends edits that are most likely to guide students from their current state towards a correct solution, based on what successful students in the past have done in the same situation. Still, the Hint Factory relies on student data being available for any state a student might visit while solving the task, which is not the case for some learning tasks, such as open-ended programming tasks. In this contribution we provide a mathematical framework for edit-based hint policies and, based on this theory, propose a novel hint policy to provide edit hints in vast and sparsely populated state spaces. In particular, we extend the Hint Factory by considering data of past students in all states which are similar to the student's current state and creating hints approximating the weighted average of all these reference states. Because the space of possible weighted averages is continuous, we call this approach the Continuous Hint Factory. In our experimental evaluation, we demonstrate that the Continuous Hint Factory can predict more accurately what capable students would do compared to existing prediction schemes on two learning tasks, especially in an open-ended programming task, and that the Continuous Hint Factory is comparable to existing hint policies at reproducing tutor hints on a simple UML diagram task.

Using Sequence Mining to Analyze Metacognitive Monitoring and Scientific Inquiry based on Levels of Efficiency and Emotions during Game-Based Learning.

Michelle Taub and Roger Azevedo
University of Central Florida
12494 University Blvd
Orlando, Florida
{michelle.taub; roger.azevedo}@ucf.edu

Abstract

Self-regulated learning conducted through metacognitive monitoring and scientific inquiry can be influenced by many factors, such as emotions and motivation, and are necessary skills needed to engage in efficient hypothesis testing during game-based learning. Although many studies have investigated metacognitive monitoring and scientific inquiry skills during game-based learning, few studies have investigated how the sequence of behaviors involved during hypothesis testing with game-based learning differ based on both efficiency level and emotions during gameplay. For this study, we analyzed 59 undergraduate students' (59% female) metacognitive monitoring and hypothesis testing behavior during learning and gameplay with CRYSTAL ISLAND, a game-based learning environment that teaches students about microbiology. Specifically, we used sequential pattern mining and differential sequence mining to determine if there were sequences of hypothesis testing behaviors and to determine if the frequencies of occurrence of these sequences differed between high or low levels of efficiency at finishing the game and high or low levels of facial expressions of emotions during gameplay. Results revealed that students with low levels of efficiency and high levels of facial expressions of emotions had the most sequences of testing behaviors overall, specifically engaging in more sequences that were indicative of less strategic hypothesis testing behavior than the other students, where students who were more efficient with both levels of emotions demonstrated strategic testing behavior. These results have implications for the strengths of using educational data mining techniques for determining the processes underlying patterns of engaging in self-regulated learning conducted through hypothesis testing as they unfold over time; for training students on how to engage in the self-regulation, scientific inquiry, and emotion regulation processes that can result in efficient gameplay; and for developing adaptive game-based learning environments that foster effective and efficient self-regulation and scientific inquiry during learning.

ABSTRACT

Each year, roughly 30% of first-year students at US baccalaureate institutions do not return for their second year and billions of dollars are spent educating these students. Yet, little quantitative research has analyzed the causes and possible remedies for student attrition. What's more, most of the previous attempts to model attrition at traditional campuses using machine learning have focused on small, homogeneous groups of students. In this work, we model student attrition using a dataset that is composed almost exclusively of information routinely collected for record-keeping at a large, public US university. By examining the entirety of the university's student body and not a subset thereof, we use one of the largest known datasets for examining attrition at a public US university ($N = 66,060$). Our results show that students' second year re-enrollment and eventual graduation can be accurately predicted based on a single year of data (AUROCs = 0.887 and 0.811, respectively). We find that demographic data (such as race, gender, etc.) and pre-admission data (such as high school academics, entrance exam scores, etc.) - upon which most admissions processes are predicated - are not nearly as useful as early college performance/transcript data for these predictions. These results highlight the potential for data mining to impact student retention and success at traditional campuses.

1. INTRODUCTION

Student attrition has long been a topic of great interest in higher education research, with government reports on attrition dating back over 100 years [31]. This interest stems from the fact that students who do not graduate are a lost investment on many fronts. For higher education institutions, limiting attrition is central to their financial sustainability as they devote scarce resources towards classes and services for non-completing students [17]. In particular, it is estimated that 30% of United States (US) first-year students do not return for their second year of post-secondary education with

US taxpayers spending nearly \$2 billion annually on educating non-returning first-year students alone [28]. Institutions are also concerned with attrition rates because they are central to estimates of institutional effectiveness, thereby affecting funding opportunities and government support [14]. Highlighting the impact of attrition at the institutional level also says nothing of its impact on students, who devote time, effort, and finances towards unfinished educational pursuits. Leaving college drastically alters career trajectories for students and those without college degrees face continually declining job growth and worsening job prospects [9].

In light of this, understanding motivations for students to drop out and possible remedies thereof is of great importance [12]. Empirical evidence to build student attrition theory has traditionally focused on survey-based research [30, 8]. However, survey instruments are often costly to implement, time-consuming for data collection, and produce results that are not always generalizable across institutions due to vastly different student profiles [34, 7, 8]. Institutional data that is routinely collected at colleges and universities (e.g. student application and transcript data) can provide an alternative data source and a way to supplement survey-based measures [8]. Leveraging data sources already in existence can add a means to more efficiently examine the student attrition problem and help institutions remedy the issue of attrition. One field that is primed to take advantage of this institutional data is educational data mining (EDM) and its focus on data-intensive techniques in educational settings [26, 4].

EDM is an emerging field with much of its research on attrition centered on massive online open courses (MOOCs) and other online environments (e.g. [35, 13]). Studying attrition in MOOCs and other online settings lends itself to expansive data collection opportunities and a detailed monitoring of students [23]. This limits the extent to which this work can be generalized to more traditional campus settings (i.e. campuses where learning is primarily on-campus, in-classroom). Meanwhile, EDM-centric work on predicting attrition at traditional campuses has been scarce and usually limited to small, homogeneous subsets of students rather than the entirety of a college student population. Additionally, the focus when predicting attrition is usually on how well it can be predicted and less so on what type of data is best for these predictions.

In this work, we predict the attrition of a large number of un-

Lovenoor Aulck, Dev Nambi, Nishant Velagapudi, Joshua Blumenstock and Jevin West "Mining University Registrar Records to Predict First-Year Undergraduate Attrition" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 9 - 18

dergraduate students ($N = 66,060$) using only their first year of academic data. The students we examine are not from a single department or major within a university. Rather, they span the entirety of a student body, thereby comprising a dataset with heterogeneous aspirations, backgrounds, and goals. In addition, we rely almost entirely on data that is routinely collected at institutions of higher education. With this data, we seek to answer two questions: to what extent can undergraduate student attrition be predicted using a limited amount of data from registrar records and what types of data from registrar records are most useful in predicting attrition. The first of these has been explored in the past while using smaller and/or homogeneous student populations; the second has not been systematically examined in the literature to our knowledge.

To answer the above questions, we mine the institutional data records at a large, public university in the US and engineer features for predictions. We then create numerous machine learning models using the engineered features and compare the performance of these models to each other. Then, we create separate machine learning models using only groups of features and not the entirety of the feature space to compare the predictive power of different subsets of institutional data. This work is an extension of our previous work on modeling student attrition using a limited amount of data [3] but where we previously focused on using the *first term's* data in generating features for prediction, we use the *first year's* in this work. We also extend our previous work to build additional machine learning models, predict attrition as defined according to two different definitions (overall graduation and re-enrollment after students' first year), and examine the types of feature subsets most useful in predictions. In so doing, we present two key findings, both of which have many implications for administrative policy in higher education:

- We demonstrate that the graduation and second-year re-enrollment of students can be predicted using data that is routinely gathered at institutions of higher education.
- We show that demographic and pre-entry features have less predictive power than data on student academics.

2. RELATED WORK

There are many examples of predicting attrition at traditional campuses. Most of these focus on small, homogeneous subsets of students. Moseley predicted the graduation of 528 nursing students using rule induction methods, obtaining high accuracies but not controlling for the number of terms/semesters examined for each student [21]. Dekker et al. looked at only the first semester grades of 648 students in the Electrical Engineering department at the Eindhoven University of Technology and were able to predict dropout with 75-80% accuracy [10]. Kovačić used tree-based methods on a similarly-sized dataset of 453 students at the Open Polytechnic of New Zealand, finding ethnicity and students' course taking patterns to be highly useful in prediction [18]. Bayer et al. looked at 775 applied informatics students at the Czech Republic's Masaryk University across three years [5]. Without limiting the amount of information available for each student, they found that including features related to students' social behavior can boost prediction accuracy by over 10% for some models. These and similar studies, how-

ever, focus on relatively small (e.g. $N < 2,000$) subgroups of students with similar academic pursuits/foci. In addition, there is little consistency with respect to the timeframes across which data is examined for each student. Other approaches to predict attrition at traditional campuses include early alert systems, which are often labor intensive and poorly funded [29]. These alert systems have been shown to positively benefit students (e.g. [16]), but usually rely on data gathered in the midst of a course or an academic term (e.g. [27, 15]), which may not always be feasible.

The work we present more closely relates to a subset of literature looking at student attrition in the context of the heterogeneity of students across an entire campus and not just a subset thereof. Our work also deals with much larger student populations than those described above and, in this sense, it more closely resembles a more recent body of literature. Delen used 8 years of institutional data on over 25,000 students at a large, public US university, predicting whether the students would return for their second year [11]. However, due to class imbalances, Delen re-sampled the majority class and ultimately used only 6,454 students for predictions. Ram et al. used data on about 6,500 freshmen at a large, public US university to predict whether students would drop out after their first semester, and for those that did not, whether they will drop out after an additional term [25]. Ram et al. supplemented data from institutional databases with student smart card transactions to infer social integration. More recently, Nagy and Molontay predicted the dropout of 15,825 students from the Budapest University of Technology and Economics using only their information prior to college entry with some success [22].

There are a few ways in which our work contributes to this body of literature. Firstly, we use a much larger dataset than has been previously examined specifically for attrition (66,060 students). We examine the entirety of a large university's student body and we do not limit the extent of heterogeneity of the students in the dataset. Additionally, we also address the question of what types of features are most useful in predicting student attrition. In particular, previous works have generally used all available data sources concurrently in determining which students will attrite. In this work, we explore what types of routinely-collected institutional data fare best when predicting attrition by comparing performance using different data subsets in isolation. Finally, we concurrently compare predictions for two different definitions of "attrition," highlighting the degree to which operationalizing the term can impact results.

3. METHODS

We describe the methods for this work by first detailing the data used in the project. We then give relevant operational definitions with respect to how we define attrition. Thereafter, we discuss the data subsets used in the predictions and the features generated. Lastly, we describe the setup of the machine learning experiments.

3.1 Data Description

We collected pseudonymized, de-identified data from the University of Washington (the University) data stewards in 2017. The University is a traditional campus setting where a vast majority of instruction is in person and face-to-face. No

personally identifiable information was collected for the students; instead, students were referenced using unique identifying keys. Table 1 shows the tables that were pulled from the registrar databases. In general, the data included information on students’ demographics, complete transcript records at the University, and information from applications to the University. We did not have any information on students’ financial aid status or economic status other than that which was derived from their ZIP code, as described below. Socioeconomic factors can play a large role in the student attrition process [6], however, we did not have access to student finances for use in this work. We also did not have access to any exit surveys from students who had either left the University or had graduated.

Table 1: Data pulled from registrar databases

Table	Description
Application Data	Information from student applications to the University including high school coursework
Guardian Data	Information on student guardians as pulled from student applications to the University
Demographic Data	Information on student demographics including date of birth, race, ethnicity, gender, etc.
Major Data	Information on majors declared by students on a term-by-term (quarter-by-quarter) basis
Test Score Data	Information on student standardized test results
Transcript Data	Information on student coursework and grades on a term-by-term (quarter-by-quarter) basis

We restricted data to high school graduates who first enrolled at the University as matriculated, baccalaureate-degree-seeking undergraduate students between 1998 and 2010 without previously attending another post-secondary institution full-time. These students are henceforth referred to as “freshmen.” The dataset included students who were in a college in high school program but excluded those who attended junior/community college full-time after high school and then transferred to the University. Because the data was pulled in 2017, we used the year 2010 as a cutoff to allow for six full years of visibility on student academics at the University before labelling a student as a “non-completion,” as defined in Section 3.2. In total, the dataset consisted of 66,060 unique freshmen entrants. We then further limited the data for each student to information through one calendar year from each student’s first enrollment at the University. This data was limited to one calendar year for all students, regardless of the number of courses they took/passed, their grades, or their backgrounds.

After joining tables of interest using the unique student identifiers, we created features for the prediction experiments by either pulling them directly from the raw data or engineering them for each student. The features were grouped in 7

groupings, which are described in Section 3.3; a comprehensive list of features and descriptions thereof is available upon request but was not provided in this writing in the interest of space. In total, there were 1,405 features and all features were generated for each student without exception.

3.2 Definitions

Ambiguity with respect to operational definitions of dropout in literature on student attrition can make it difficult to compare results across studies [24, 33]. There are numerous ways in which attrition has been defined in existing literature, be it students dropping out from a particular course (e.g. [21]), re-enrolling after their first term (e.g. [1]), re-enrolling after their first year (e.g. [11]), graduating on time (e.g. [3]), or reaching some other relevant milestone (e.g. [10]). In this work, we defined attrition in two ways and analyze both. We examined attrition from students’ first year to their second (“re-enrollment” and “non-re-enrollment”) as well as looking at whether a student graduated on time (“graduate” and “non-completion”). We do not examine attrition on a term-by-term basis because of the relatively few students who leave the University after only a single term, as discussed in Section 4.1. We operationally defined non-completion and re-enrollment as described below.

3.2.1 Non-Completion

We defined “non-completion” as any freshman student who did not graduate with a baccalaureate degree from the University within 6 calendar years of first entry to the University. We defined a “graduate” as a freshman who graduated from the University with a baccalaureate degree within 6 calendar years of first enrollment. The University uses a quarter term system and we used the span of four consecutive academic quarters as a measure of one calendar year. Six calendar years for graduation was thus the span of 24 consecutive academic quarters. This definition of non-completion only accounted for students’ first baccalaureate degree and did not take into account double-majors or double degrees. For example, if a student was simultaneously pursuing two baccalaureate degrees but only graduated with one in five years, they would be a graduate; alternatively, if the student had graduated with both degrees but during their seventh year, they would be considered a non-completion. Because we focused on registrar records from a single institution, defining non-completion in this manner does not take into account students’ academic progression after leaving the University. This is because we only had access to registrar records from a single institution and did not track students across multiple institutions - they could have very well transferred from the University and graduated in good standing.

We accounted for students who took part in a college in high school program by converting their transferred credit total to a count of academic quarters completed while assuming typical full-time enrollment at the University. For example, if a student completed 30 credits in a college in high school program, we converted this credit total to a count of terms completed at the University (in this case, 2, as students typically take 15 credits per term). We rounded the result from this conversion where appropriate. We then deducted this number when determining whether the student had graduated within an appropriate amount of time.

3.2.2 Re-Enrollment

We defined “re-enrollment” as a student who completed at least one additional course within one calendar year of the end of their first calendar year at the University (i.e. within 4 academic quarters from the end of their first year). “Non-re-enrollments” were students who were not re-enrollments. In this work, the definitions of graduation and re-enrollment were treated mutually exclusive in that all graduates were not necessarily re-enrollments. It should be noted that the University requires students who do not enroll for two consecutive terms without an excused leave to be re-admitted at the discretion of the University.

3.3 Feature Groupings

For every student, we engineered the subsets of features that are described below. For all student grades, we calculated a grade percentile and a z-score by comparing each students’ grades to the grades of all undergraduate students who had taken the same course at the same time. References to grades include the student’s GPA (on a 4.0 scale), their percentile score (from 0-100), and their z-score for courses (representing the number of standard deviations from the mean, assuming a normal grade distribution). References to “performance” for the feature groupings include grades and credits earned, at the least. In some cases, references to performance may also include the number of graded credits earned (versus courses taken pass-fail) and the number of credits attempted. A brief description of each of the feature subsets is provided in Table 2.

Table 2: Data subsets used in predictions

Subset	Description
Base Data	Year and quarter of University entry (included with every other data subset)
Demographic Data	Non-academic data prior to entry to the University, including demographics
Department-level Data	Measures of performance aggregated by course department
First-Year Summary Data	Aggregated measures of academic performance during first year
Grouped Course Data	Measures of performance aggregated by course number and STEM gatekeepers
Major Data	Counts of majors declared on a term-by-term basis
Pre-Entry Data	Academic data prior to entry to the University.

3.3.1 Base Data

Base data consisted of only three features and was included in the feature space when making predictions using every other data subset described. The base data included students’ calendar year of entry to the University, their quarter of entry to the university (i.e. which of the four academic quarters was a student’s first; ranging from 1 to 4, with 1, 2, 3, and 4 corresponding to winter, spring, summer, and autumn academic quarters, respectively), and a quarter-year variable which consisted of students’ year of entry multiplied by 4 and added to the quarter of entry to create a relative

time scale. These features were included to account for any time-related variation in graduation rates.

3.3.2 Demographic Data

Demographic data consisted of student’s non-academic information prior to entry to the University. This included, but was not limited to, students’ gender, race, ethnicity, age at college enrollment, veteran status, and student athlete status. We also included information from students’ application to the University, such as information on the students’ high schools (excluding high school grades), parents’ educational attainment, and students’ ZIP (postal) code, which was either pulled from their high school information or, when unavailable, from their university application. We joined students’ ZIP codes with 2015 US census data¹ to find the average income and educational attainment in each ZIP code. We also included the distance from the University to each student’s home ZIP code. Features derived from ZIP codes were the only features from sources external to the University’s registrar databases.

3.3.3 Department-level Data

Department-level data consisted of student performance in course offerings grouped by course prefix. For example, this included performance in all BIOL (biology) courses grouped together, performance in all HIST (history) courses grouped together, etc. We excluded course prefixes wherein at least 10 students from the dataset did not take a course. In all, this included 200 unique course prefixes and 1000 features, with GPA, percentile grade, z-score, credits earned, and graded credits earned calculated for each prefix. We used department-level data instead of individual course data after preliminary modeling using individual courses did not yield strong results. The expansive feature space when engineering features across individual courses also significantly increased the requisite computational power/time for modeling and we decided against pursuing this further.

3.3.4 First-Year Summary Data

First-year summary data consisted of aggregate measures of students’ first year at the University. This included, among other things, students’ course performance, credits taken, number of courses failed, number of quarters enrolled, and enrollment in a freshman seminar courses. The first-year summary data also included aggregate measures of students’ performance in their first, second, third, and fourth quarters as well as student performance in the last academic quarter for which they were enrolled during their first year (regardless of which quarter it was). We also included differences between students’ performance in successive quarters.

3.3.5 Grouped Course Data

Grouped course data consisted of student course performance grouped either by course number or by performance in “STEM gatekeepers.” To group courses by course number, we aggregated performance across all courses that were numbered below 100, from 100-199, from 200-299, from 300-399, and 400+. The course numbering generally reflected whether the course was designed to be taken by lowerclassmen or upperclassmen and, in some cases, also indicated

¹From the US Census Bureau’s American Fact Finder

during which year students typically took the course. STEM gatekeepers refer to introductory science, technology, engineering, and math (STEM) courses which often function as pre-requisites for STEM majors and degrees. These gatekeeper courses tend to be highly competitive and performance in these courses is a key determinant of whether a student will be accepted into any of the highly competitive STEM majors. We grouped the performance in STEM gatekeepers by course department and topic (e.g. the calculus series, the general chemistry series, the organic chemistry series, etc.) as well as across all STEM gatekeepers.

3.3.6 Major Data

Major data consisted of counts of students' major declarations during their first academic year. In most cases, students entered the University with a "pre-major" designation before declaring their major(s) of interest some time during their first or second year. These pre-major designations varied based on field of interest (e.g. pre-engineering, pre-nursing, pre-health, etc.). Students' majors were recorded on a per-quarter basis by the University (once per quarterly transcript record) and we tallied the counts of major declarations for each student across the entirety of their first year. For example, a student who declared a math major in their first two quarters only to switch to geography in their third quarter and then add a history double major in their fourth quarter would have the values 2, 2, 1 in the math major, geography major, and history major features, respectively.

3.3.7 Pre-Entry Data

Pre-entry data consisted of students' academic information prior to attending the University. This included, among other things, students' entrance exam scores, high school GPA, high school coursework, and college in high school program participation and performance. We did not include any information on students after their enrollment at the University in the pre-entry data.

3.4 Machine Learning and Predictions

We randomly divided the students into training and test sets using a 80-20 split (N in training = 52,848; N in test = 13,212). We used the same test set when evaluating the predictive performance of each of the models to allow for direct comparisons to be made. The data was highly skewed with graduates and re-enrollments comprising 78.5% and 93.1% of all the data, respectively. Graduates and re-enrollments comprised 78.0% and 92.9% of the test data, respectively. Though dealing with class imbalances is of great interest when examining freshmen attrition [32], we did not use any balancing techniques as we wanted to work with the data in its original, unaltered form. We scaled the training data by subtracting the median of each feature and dividing by the respective feature's interquartile range. We subsequently scaled the test data using the scaling values for each feature from the training data.

We used five different machine learning models to predict each student's graduation and re-enrollment: regularized logistic regression (LR), K-Nearest Neighbors (KNN), random forests (RF), support vector machines (SVM), and gradient boosted trees (XGB). We trained each model across the entirety of the training data and used the same training

instances to train each of the models. We trained each model separately to predict graduation and re-enrollment. We tuned model hyperparameters for each model using 5-fold cross validation on the training data, after which the models were re-trained on the entirety of the training data using the tuned hyperparameters. We report final error metrics and performance on the test set, which was consistent across all models, regardless of whether predicting graduation or re-enrollment.

After developing predictive models using all features, we created regularized logistic regression models using each of the 6 feature subsets highlighted in Section 3.3 in isolation. The base data (see Table 2) was included in the feature space for each data subset. The rationale behind using regularized logistic regression for these models is further discussed in Section 4.3. We understand that an alternative approach would be to test all the models listed above for each of the data subsets to find the best performing model/subset combinations. That said, we believe our approach was still suitable for comparing different data subsets. When modeling using data subsets, we used the same observations as before to train each of the models and, as before, we developed a separate model for predicting graduation and re-enrollment for each of the data subsets. As such, the *training instances* were the same across models but the *training features* differed depending on the feature subset used. We tuned the regularization strength for these regularized logistic regression models using 5-fold cross validation on the training dataset and we report results on the test set.

4. RESULTS AND DISCUSSION

4.1 Student Characteristics

We show the number and proportion of graduates and re-enrollments in Figure 1. In all, 78.5% of students were labelled graduates while 93.1% of students were labelled re-enrollments. These proportions were verified with the University's office of institutional analysis. Such highly skewed data towards graduates and re-enrollments can be expected in a large, tier-1 research university setting where there has been considerable, long-standing effort to improve the overall attrition rate over time. That said, it must also be noted that at an institution with such a large student population, even small fractions of the student body represent hundreds of students on an annual basis. Across the timeline of the dataset (13 cohorts), 14,196 non-completions and 4,593 non-re-enrollments represent 1,092 and 351 students on an annual basis, respectively.

We show the cumulative percentage of students who either graduated or left the University across time in Figure 2. We used the first year as a cutoff for the data because, historically, a large number of students decide whether they will continue with their higher education pursuits during and immediately after their first year [28]. As such, developing models that can predict whether students will re-enroll for a second year and whether they are on a trajectory towards successful graduation could help administrators and academic advisors more effectively develop and deliver interventions directed towards students in need of assistance. When examining the data, 27.5% of all non-completions leave the university prior to the start of their 2nd year, 51.9% of non-completions leave the University between their 2nd and 6th

Figure 1: Counts and percentages of classes in the dataset. Definitions are provided in Section 3.2.

year, and 20.6% continued to be enrolled at the University after their 6th year. The difference in number between non-completions who did not return for their 2nd year and non-re-enrollments can be attributed to non-re-enrollments who later returned to the University and graduated on time. Less than 5% of non-completions and less than 15% of non-re-enrollments left the University after only one term, leading us to not examine attrition after the first and second terms. In settings where attrition rates are higher after students' first and second terms, it may be more relevant to examine the performance of classifiers after one or two terms.

Figure 2 also shows that a majority of graduates (65.6%) completed their degrees during their fourth year at the University. The mean and median completion time for all graduates was 16.6 and 15.0 calendar quarters, respectively, from first enrollment. This is particularly apparent due to the near-sigmoidal shape of the cumulative graph for graduates, with a sharp rise during students' fourth year. We also see that there is a relative lack of students who graduated prior to the start of their third year. This highlights the difficulty in predicting graduation based on students' first year - a student typically does not graduate until several years later, during which a host of influences can shape an academic trajectory, be they personal, financial, or academic.

4.2 Predictions Using Different Algorithms

Table 3: Prediction results using all data features. Baseline values are based on test set.

Model	Graduation		Re-Enrollment	
	Accuracy	AUROC	Accuracy	AUROC
Baseline	78.0%	0.500	92.9%	0.500
LR	83.2%	0.811	95.0%	0.882
RF	83.1%	0.806	95.3%	0.887
XGB	83.0%	0.806	95.1%	0.885
KNN	82.5%	0.798	94.8%	0.876
SVM	78.0%	0.780	92.9%	0.862

We show the performance of each of the models using the entirety of the feature space in Table 3. The baseline measure in the Table refers to the majority class compositions in the test set. Generally speaking, most of the models had a similar comparative performance for each prediction task (i.e. predicting either graduation or re-enrollment). This hints at

Figure 2: Cumulative graduation and non-completion curves of students. Years and quarters are relative to the time of first enrollment. The dotted line indicates the point to which data is limited for each student. Only students' first six years are shown, per the definition of "graduate."

an effective ceiling with respect to predictive power from the types of features being used (i.e. ones pulled from registrar records) and that additional representations of the student experience (be they academic or social) should be incorporated. Alternatively, a more complex predictive model (e.g. deep neural networks) may also fare better in making these predictions. That said, given the data used, the models are able to predict the eventual graduation and re-enrollment of students fairly successfully, as evidenced by the relative improvements over baseline values for both prediction tasks.

For predicting graduation, logistic regression was the best-performing model, followed by random forests. When predicting re-enrollment, random forests performed the best, followed by gradient boosted trees and logistic regression. These results are generally in line with our previous work on similar tasks, where we found that logistic regression tends to work well compared to other models for predicting graduation and STEM attrition [2]. When examining the worst-performing models, the SVM model made predictions that consisted entirely of the majority class when predicting both graduation and re-enrollment, as seen by the models' accuracy being the same as the baseline values. Such results are typical of classifiers without much predictive strength on a dataset consisting of highly disproportionate classes. In this specific case, it may be remedied by using alternate kernels for the model, which we did not explore in this work.

We show the ROC curves for the models in Figure 3. These curves further illustrate the lack of differentiation with respect to model performance. For the same prediction task, the resulting ROC curves across the models were nearly identical with little difference in curvature. The more notable difference was when comparing the ROC curves for predicting graduation with those for predicting re-enrollment, as the curves for predicting re-enrollment were more prominently convex compared to those for predicting graduation. These curvatures, along with the metrics shown

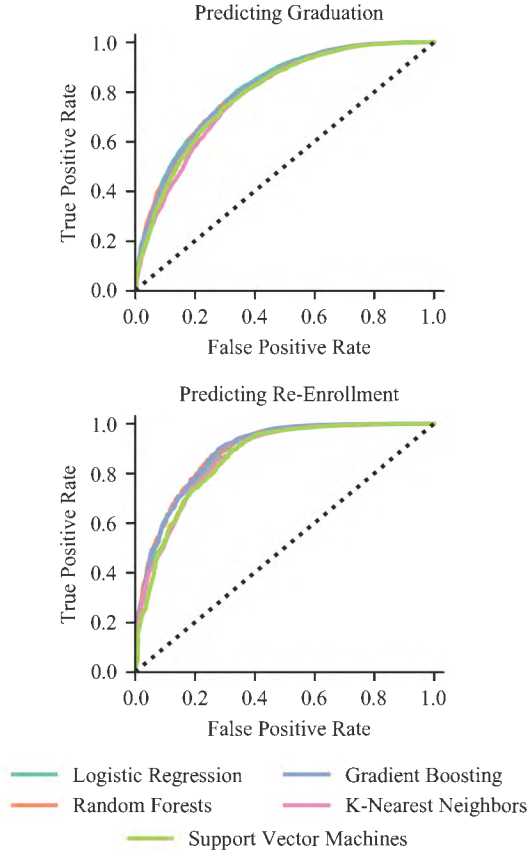

Figure 3: Receiver operating characteristic curves when using different machine learning models.

in Table 3, demonstrate that predicting students’ eventual graduation is a more difficult task than predicting students’ re-enrollment. We expected this as the cutoff for the data used in the predictions (i.e. students’ first year) was near the point at which a student is classified as a re-enrollment (after their second year) but was much earlier than when a student was classified as a non-completion (after their sixth year). This helps highlight the degree to which differing operational definitions of attrition can vastly alter the perceived predictive strength of these classifiers. For other scenarios, alternate definitions of attrition may be more appropriate and the effectiveness of efforts to build predictive models will be colored by these definitions and institutional contexts.

We show the confusion matrices for the best models for predicting graduation and re-enrollment (logistic regression and random forests, respectively) in Figure 4. These matrices show a lower rate of false negatives for the models but a higher rate of false positives (i.e. students incorrectly classified by the models as having graduated or re-enrolled). To better understand this higher rate of false positives, we examined the complete transcript records of students who were classified accordingly. Across the false positives, we found numerous instances of non-completions and non-re-enrollments who had left the University with relatively strong grades in comparison to their graduating and

Figure 4: Confusion matrices when examining the top performing algorithms for predicting graduation (LR, left) and re-enrollment (RF, right).

re-enrolling peers. These students also often appeared to be pursuing very competitive majors and/or appeared to have rigorous post-graduation plans (e.g. pre-medical and pre-dental students). Many of these students remained in a pre-major state prior to their departure, indicating that though they had relatively strong grades, they likely were not able to enter into their degree program(s) of choice for various reasons and had to leave the University to pursue these ambitions as a result. Unfortunately, the University does not have a centralized major application database for admissions and rejections to specific majors. Having so could shed light on much of the motivation behind these students’ desire to leave the University and if it was, in fact, motivated by not getting into competitive majors. That said, the fact that many of these students were academically similar to their graduating and re-enrolling counterparts further illustrates why there appears to be an effective ceiling with respect to predictive power using the given data, as seen in Table 3.

From a practical perspective, it should be noted that the classification thresholds for these models were not tuned with respect to either sensitivity or specificity. In practice, when developing institutional systems to identify students at-risk of leaving, it may be useful to raise the classification threshold when predicting whether a student will graduate or re-enroll, thus favoring lower recall at the expense of higher precision. This would effectively reduce the number of students who are predicted to graduate but in actuality do not (i.e. false positives) at the expense of more false negatives, which could be more acceptable when developing an alert system for students at risk of dropping out.

4.3 Predictions Using Different Data Subsets

After examining the results from predicting graduates and re-enrollments using all features, we used regularized logistic regression to predict graduation and re-enrollment using subsets of the data. We used logistic regression after we saw that it performed very well relative to other models for both prediction tasks (see Section 4.2) and because it had relatively fast training times due to having fewer hyperparameters to tune. This allowed us to more efficiently train the 12 different models that were needed when examining the performance of specific data subsets (i.e. separately modeling graduation and re-enrollment while using 6 different

Table 4: Prediction results using specific data subsets. Baseline values are based on test set.

Subset	Graduation		Re-Enrollment	
	Accuracy	AUROC	Accuracy	AUROC
Baseline	78.0%	0.500	92.9%	0.500
All	83.2%	0.811	95.0%	0.882
FY-Sum.	83.0%	0.795	94.9%	0.855
Department	82.3%	0.788	94.6%	0.847
Grouped	82.5%	0.781	94.6%	0.845
Major	79.9%	0.661	94.2%	0.768
Demo	78.0%	0.634	92.9%	0.643
Pre-Entry	77.3%	0.630	92.9%	0.616

data subsets in isolation for each).

We show the results when using data subsets in Table 4 alongside the performance of the logistic regression classifier from Section 4.2. Transcript-based features tended to perform better than information on students’ prior to their enrollment at the University. More specifically, demographic data and pre-entry information did relatively poorly in predicting both graduation and re-enrollment. Intuitively, this is not a surprise as the admissions process at highly-competitive universities tends to be fairly selective with an emphasis on supporting and sustaining a successful yet diverse student body. Additionally, such institutions may already have efforts in place to reduce demographic disparities for student success. Meanwhile, when looking at transcript-based data subsets, first-year summary data performed the best with performance that was similar to using the entirety of the data. This is particularly noteworthy as the first-year summary data contained fewer features than the other transcript-based data subsets but was centered on summaries of performance across time rather than aggregations across course departments/numberings.

These findings are particularly interesting in light of work by other researchers. For instance, Nagy and Molontay found that attrition could be accurately predicted using what we outline as demographic and pre-entry features alone [22]. However, we do not see similar success here. We believe this could be due to vastly different educational settings and student profiles (e.g. here, most students tend to graduate/re-enroll while Nagy’s student population primarily dropped out). In earlier work, Dekker et al. found that transcript-based features tend to have more predictive strength than pre-entry features, but examined this across rather limited data subsets [10]. Our results echo this finding. Recently, Manrique et al. found that attrition could be predicted using student performance in a few key courses [20]. Here, we find that aggregates across the first year tend to work better than more fine-grain representations of course-taking (e.g. grouping classes by course prefix and numbering). As discussed in Section 3.3.3, we decided against using individual course representations in this work.

We show the ROC curves for the regularized logistic regression models using each of the data subsets as well as the entire feature space in Figure 5. The fact that demographic and pre-entry data gave generally worse performance than

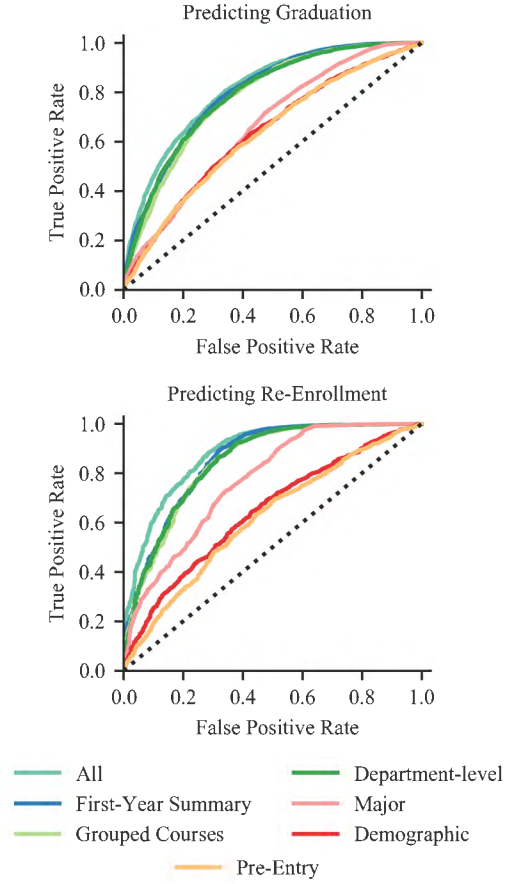

Figure 5: Receiver operating characteristic curves when using different subsets of data.

transcript-based features is very much apparent from the ROC curves. Data on majors, meanwhile, tended to perform worse than other transcript-based features but better than demographic and pre-entry data. The fact that using data on majors did not yield particularly strong results likely relates to the fact that most students in the dataset were in a pre-major state across their first year and formally declared their major of interest later in their undergraduate careers. As noted above, a centralized major application system was not available, else it could have been leveraged in addition to data on majors to draw a more clear picture of student academic interest. The other transcript-based datasets, meanwhile, had very similar curvatures for the ROC curves when predicting both graduation and re-enrollment.

We show confusion matrices from using the best-performing data subset in Figure 6. The best-performing data subset for both prediction tasks was first-year summary data. By comparing these confusion matrices to those shown in Figure 4, it can be seen that using just a limited subset of features tends to classify the data similarly to models built on the entirety of the data. This is true not only in terms of how effective the models are in making predictions, but also with respect to the relatively high rate of false positives seen across all four matrices.

Figure 6: Confusion matrices when examining the top performing data subset for predicting graduation (left) and re-enrollment (right). The top performing data subset was the same for both tasks (first-year summary data).

5. FUTURE DIRECTIONS

We believe the findings regarding the data subsets have wide-ranging policy implications, particularly for identifying students at risk of dropping out in large, public universities. In such settings, there may be longstanding effort to decrease demographic disparities with respect to attrition and, as a result, transcript records may be more viable as features in predictive models than pre-entry/demographic information. Furthermore, these settings may also be resource-constrained with respect to time available for staff to hand engineer features. In such settings, knowing which features would be most predictive of attrition without the need to hand-engineer features across the entirety of data available to institutions could save time and effort in building models. We have had conversations with administrators at the University for better interpreting our results and improving the processes for identifying students in need of assistance.

Another direction of interest is better understanding the features used in predicting attrition. This includes not only further examining key individual determinants of attrition, as we have done in previous work [3, 2], but also finding the best combination of features across the subsets. We would like to examine this “minimum viable feature space” in the context of data available in registrar databases as well as investigate the degree to which these features relate to established theory on student attrition [12].

6. CONCLUSIONS

In this work, we use data from the registrar databases of a large, public US university to predict both graduation and re-enrollment using information limited to students’ first calendar year at the university. We do this using a dataset of students that spans the entirety of the university student body and is thus much larger than previous studies predicting student attrition ($N = 66,060$). In so doing, we demonstrate that both graduation and re-enrollment can be effectively predicted using features generated from data that is routinely collected at institutions of higher education. Additionally, we also examine the degree to which specific subsets of registrar data can be useful in predicting attrition, finding that transcript-based features tend to outperform features

based on student histories prior to college. This implies that effective strategies for intervention can be outlined based on registrar records.

Predicting re-enrollment after students’ first year was a much more tractable task than predicting graduation. This can be attributed to the fact that predicting graduation necessitates predicting academic success years into the future from the point to which data was limited whereas predicting re-enrollment is within a much shorter timeframe. Considering the unpredictable influences that cause students to leave college prior to graduating (e.g. financial limitations, personal hardships, etc.), a more reliable prediction task may be to examine whether a student will return on a term-by-term basis. This could be particularly useful to develop alert systems to identify students at risk of dropout. However, this was not explored in this work due to the relatively few students who left the University after a single term.

We found that there appears to be an upper limit for predictive power for our dataset. This demonstrates the limitations when relying solely on registrar data and shows the need for additional features on the student experience to improve predictive power. Some potential features of interest include measures of social integration on campus and of financial aid. Better understanding student aspirations beyond simply using declared majors could also be of interest, especially using alternate representations of student course-taking behavior, as shown recently by Luo and Pardos [19].

Lastly, we show that features generated from transcript records, particularly aggregates and summaries of students’ academics, perform better for predictions than demographic and pre-entry data. Much of this is likely due to the selectivity of the University and its admissions policy. Nevertheless, it demonstrates how useful transcript data can be for such prediction tasks in contrast to information on students prior to college. We demonstrate that using subsets of data from registrar databases (in this case, aggregates of students’ first year) can be nearly as effective for predictions as hand-generating a wide swath of features from different institutional data sources.

7. ACKNOWLEDGMENTS

The authors would like to thank the data stewards at the University of Washington for their assistance in obtaining the data used in this work.

ABSTRACT

For the development of successful human-agent dialogue-based tutoring systems, it is essential to understand what makes a human-human tutorial dialogue successful. While there has been much research on dialogue-based intelligent tutoring systems, there have been comparatively fewer studies on analyzing large-scale datasets of human-human online tutoring dialogues. A critical indicator of success of a tutoring dialogue can be student satisfaction, which is the focus of the study reported in the paper. Specifically, we used a large-scale dataset, which consisted of over 15,000 tutorial dialogues generated by human tutors and students in a mobile app-based tutoring service. An extensive analysis of the dataset was performed to identify factors relevant to student satisfaction in online tutoring systems. The study also engineered a set of 325 features as input to a Gradient Tree Boosting model to predict tutoring success. Experimental results revealed that (i) in a tutorial dialogue, factors such as efforts spent by both tutors and students, utterance informativeness and tutor responsiveness were positively correlated with student satisfaction; and (ii) Gradient Tree Boosting model could effectively predict tutoring success, especially with utterances from the later period of a dialogue, but more research effort is needed to improve the prediction performance.

1. INTRODUCTION

Intelligent tutoring systems (ITS) are computer systems that are designed to act as human tutors and provide personalized instruction or feedback to students in online learning environments [3, 41]. Ultimately, ITS aim at replicating the benefits of one-to-one tutoring in contexts where students cannot receive such tutoring during the learning process

[49]. In the past decades, numerous researchers have been actively involved in the investigation and development of various types of ITS, among which representative examples include AutoTutor [19], BEETLE [16], ASSISTments [25], and Cognitive Tutor [36]. More importantly, these systems have been applied in different educational contexts for hundreds of thousands of students to use and have facilitated student learning. With the aid of ITS, students with an internet connection can receive guidance tailored to their needs and enhance their learning anytime and anywhere. At the same time, instructors and educational institutions can improve their teaching quality and educational programs by analyzing the fine-grained data collected by ITS [1, 3].

Figure 1: A tutoring dialogue example.

A special class of ITS is dialogue-based intelligent tutoring systems such as AutoTutor and BEATTLE, which emphasize the use of human-agent dialogue in one-to-one tutoring. Such systems have been built on advances in psycho-/sociolinguistics, computational linguistics, and natural language processing [14, 35] to create productive learning experiences in human-agent dialogue tutoring.

In line with [47], we argue that the future development of

Guanliang Chen, David Lang, Rafael Ferreira and Dragan Gasevic "Predictors of Student Satisfaction: A Large-scale Study of Human-Human Online Tutorial Dialogues" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 19 - 28

dialogue-based systems can benefit greatly from the analysis of massive datasets collected in online tutoring. Online tutoring has been promoted by a growing number of applications, e.g., Chegg¹, Skooli² and Wyzant³, that offer human-human online tutoring at scale and the learning subjects covered by these applications include math, science, language learning, humanities, etc. Specifically, we are interested in understanding what constitutes successful human-human online tutoring. In this paper, we report on the findings of a study that looked at factors that predict student satisfaction with human-human online tutoring.

The analysis of human-human online tutoring requires consideration of factors that shape the entire tutorial process. Online tutoring, especially helping students to solve problems, is a complex process, in which a student is expected to clearly explain the problems to be solved to a tutor and the tutor is expected to use her knowledge as well as appropriate tutoring strategies to guide the student to solve the problems. The success of such a process depends on many factors, e.g., whether the student clearly explains the problem, whether the tutor asks appropriate questions to guide the student, and whether the tutor provides sufficient emotional support. As shown in the example in Figure 1, the student ended the tutoring session because the tutor did not respond to the student in a timely manner and the student only rated the tutoring session as 1 on the scale of (1,5), which indicated that the student was not satisfied with the tutoring service at all and thus the tutorial dialogue was unsuccessful.

To our knowledge, few studies have attempted to identify the crucial factors that are correlated with the success of a tutoring session. Thus, our work aimed at (i) identifying factors that are correlated with the success of a dialogue-based tutoring session, and further (ii) utilizing the identified features as input to a state-of-the-art machine learning model to predict the tutoring success. Formally, our work was guided by the following research question:

RQ: What factors are related to student satisfaction with online tutoring service?

By investigating the RQ, we expected to (i) help tutors in existing online tutoring systems to better direct their efforts in guiding students, and (ii) inform the design of future dialogue-based ITS.

To this end, we first formulated a set of hypotheses about potential factors that were correlated with the success of a dialogue-based tutoring, which were grounded in previous research findings on online tutoring or relevant educational topics. Then, we conducted an extensive analysis of a large-scale dataset provided by a company offering online tutoring services to students, which contained transcripts of over 15,000 dialogue-based tutoring sessions generated by more than 5,000 students, to test the formulated hypotheses. Based on the analysis, we designed a set of 325 features and used these features as input to a state-of-the-art

machine learning model (i.e., Gradient Tree Boosting) to predict whether a tutorial dialogue would be successful or not.

Experimental results showed that the success of a dialogue-based online tutoring session was associated with factors such as the efforts made by both tutors and students, the informativeness of the utterances, and the sentiment polarity conveyed through the utterances. We further showed that Gradient Tree Boosting was an effective method in predicting the success of tutoring sessions. In particular, we observed that the utterances from the later period of a tutoring session (e.g., the last 20% utterances in a dialogue) could deliver prediction accuracy comparable to that using the whole dialogue as input, and more research effort can be invested to further boost the prediction performance.

2. RELATED WORK

Our work is mainly related to research on educational dialogue analysis [39]. One common theme that has been investigated for years is the development and refinement of a coding scheme for educational dialogue acts [30, 38]. For instance, by building upon the language-as-action theory, [21] proposed a coding scheme that attempts to map utterances to their inherent functions in a dialogue and validated the effectiveness of the proposed scheme in two different learning contexts (one from primary school and the other from secondary school).

Another common strand of work in the field is the investigation of the relationship between tutorial dialogues and student performance [29]. For example, [47] adopted correlation analysis to capture the effects of dialogues on student performance. In particular, the dialogue acts of tutors (e.g., those related to providing explanations) were found to be significantly predictive of students' learning gain. Similarly, [5] found that the choice of corrective tutorial acts adopted by tutors, which serves as an approach to deal with incorrect problem-solving actions, has a significant influence on students' learning gain. In a different vein, [32] measured the quality of a tutorial dialogue with the Classroom Assessment Scoring System-Secondary observational instrument and demonstrated that the quality of educational dialogues was positively associated with student performance. Other relevant works include [13, 17, 24, 31].

Compared to the related works described above, our work distinguished itself in several aspects. Firstly, our work aimed at discovering factors that are related to student satisfaction instead of student performance, though both of them can be regarded as indicative predictors for the success of a tutorial dialogue. Secondly, our work analyzed various types of factors associated with student satisfaction (which are described in Section 3), while prior works have mainly analyzed one or two specific types of factors, e.g., dialogue acts [5, 47] and dialogue quality [32]. Thirdly, the tutorial dialogue dataset used in our work consists of dialogues collected from over 15,000 tutoring sessions initialized by more than 5,000 students, while previous work often used datasets containing a few hundred tutorial dialogues generated by dozens of students.

3. APPROACH

In this section, we first describe the dataset we used for analysis. Then, we outline and justify the hypotheses upon which we grounded our work to explore factors that are associated with student satisfaction, and then introduce the method we used to test these hypotheses. Lastly, we describe the machine learning model for predicting student satisfaction.

3.1 Dataset

The dataset used in our work was prepared by an educational technology company that provides on-demand tutoring services via a mobile application and covers topics including mathematics, chemistry, and physics. With the mobile application, a student can take a picture of the problem she encounters or directly write down the problem and select the category to which the problem belongs to. Then, the student will be connected to a professional tutor who can guide the student to solve the problem by leveraging texts and pictures to communicate. Originally, the dataset consisted of dialogues of 18,203 tutoring sessions, which accounted for over 7,000 tutoring hours. To ensure the validity and generalizability of the experimental results, we filtered out dialogues with less than 10 utterances or of duration less than 60 seconds. This was carried out because tutors were unlikely to deliver meaningful tutoring in those sessions.

Table 1: Dataset statistics.

Category	Row ID	Metric	Value
Basic statistics	1	# Sessions	15,756
	2	# Utterances	1,250,270
	3	# Tutors	116
	4	# Students	5,468
	5	Avg. ratings	4.22
Dialogue length	6	Avg. session duration (mins)	28.75
	7	Avg. # utterances / session	79.35
	8	Avg. # words / session	610.87
	9	Avg. # unique words / session	183.80
Activeness	10	Avg. % utterances sent by tutors	57.92
	11	Avg. % words sent by tutors	78.02
	12	Avg. % new words sent by tutors	74.92
Platform experience	13	Avg. # sessions guided by tutors	135.83
	14	Avg. # sessions owned by students	2.88

After filtering, the dataset contained a total of 15,756 dialogues generated by 116 tutors and 5,468 students together, as described in Table 1. It is noteworthy that more than 79% of the dialogues received a rating of 4 or 5 (out of a scale of (1, 5)), as shown in Figure 2, and only about 16% of the dialogues were of rating 1 or 2. This indicates that most of the students were satisfied with the help they received from tutors and those tutoring sessions were successful.

To enable a better understanding of the characteristics of the tutor/student behavior in online tutoring, we further analyzed the dataset from the following perspectives: the length of dialogues, how active tutors/students were in dialogues, and the experiences of tutors/students in using the tutoring platform, and the results are given in Table 1 (Rows 6-14). Firstly, the average duration of all tutorial sessions is about 29 minutes, and we observed that about 50% of the sessions

Figure 2: The distribution of student ratings for tutoring sessions.

Figure 3: The distribution of the duration of tutoring sessions.

Figure 4: The distribution of the number of unique words in dialogues.

were less than 20 minutes, as shown in Figure 3. On aver-

age, about 80 utterances and 610 words were contained in a dialogue. However, we found only 184 unique words were contained in a dialogue, which was only about 30% of the average number of words used in a dialogue. In fact, most of the dialogues (over 70%) only contained 50~250 unique words (Figure 4). This is in line with previous research finding [6], i.e., people tend to use a relatively small number of words during the conversational process. Also, we observed that tutors were more active than students, i.e., on average, 58% of the utterances in a dialogue were sent by tutors (as shown in Figure 5, tutors sent 50%~70% of the utterances in almost 80% of the dialogues). We had a similar observation when analyzing the average fraction of words sent by tutors, i.e., in over 70% of the dialogues, tutors sent 70%~90% of the words. In particular, 75% of the new words (i.e., words which never appeared in previous utterances) were from tutors. In fact, tutors were in charge of introducing 60%~90% of the new words in 88% of the dialogues (as depicted in Figure 6). This implies that, most of the dialogues were led by the tutors, e.g., tutors were responsible for introducing new concepts to help students solve the problem and guiding students by providing detailed explanations. In terms of platform experience, on average, tutors guided more than 135 sessions, while students only had less than 3 sessions. A detailed analysis revealed that only 43% of the students used the tutoring service for more than once.

Figure 5: The distribution of the fraction of utterances sent by tutors in dialogues.

Figure 6: The distribution of the fraction of new words sent by tutors in dialogues.

3.2 Research Hypotheses

Based on prior work, we can make the following hypotheses related to our RQ.

H1 *The more efforts a student/tutor spends in a tutorial dialogue, the more likely the dialogue will be successful.*

The efforts spent by students in learning (e.g., the engagement with course materials) have long been regarded as predictive indicators of their performance [8, 15, 37]. Similarly, we hypothesized that the amount of effort spent by tutors, which directly determines how much help students can receive, also affect students' performance and tutoring success.

H2 *The more informative the utterances sent by a student/tutor are, the more likely a tutorial dialogue will be successful.*

Generally, informative tutoring feedback provided by tutors to students plays a positive role in assisting students in most learning contexts [33]. Here we argue that the informativeness of student utterances also contributes to the success of a tutoring session because it helps tutors quickly understand the difficulties faced by students and correspondingly come up with effective tutoring strategies to help the students.

H3 *The less time a student spends waiting to receive a response from a tutor, the more likely a tutorial dialogue will be successful.*

Previous research on investigating the design and delivery of feedback in online learning environments showed that not only the feedback itself but also the timing of feedback provision impacted student learning [27]. As suggested in [42], effective feedback should be timely so that students can recall the steps of addressing a learning task. Given the fact that a tutoring session is initialized by a student seeking help to solve a problem, this, to a certain extent, implies that the student lacks necessary knowledge but is eager to receive responses from a tutor and solve the problem.

H4 *The higher the lexical entrainment of a tutorial dialogue is, the more likely the dialogue will be successful.*

[6] pointed out that people involved in a conversation tend to coordinate with each other in terms of the words they use (so-called *lexical entrainment*), e.g., both the tutor and the student mentioned the word *triangle* in the dialogue in Figure 1. [34] argued that lexical entrainment is key to facilitate both production and comprehension in dialogues, and more importantly, correlated with task success.

H5 *The less complex the utterances sent by a student/tutor are, the more likely the dialogue will be successful.*

[40] suggested that, in the setting of classroom-based education, tutors should intend to gradually increase the complexity level of their verbal communication with students so as to foster students' level of competency. However, in the setting of online tutoring, in which a tutoring session usually lasts no more than half an hour (as shown in Section 3.1) and the learning task is relatively simple (e.g., solving a math problem), we hypothesized that the complexity level of tutor/student

utterances would be negatively correlated with the tutoring success as complex utterances usually take more time to understand and respond.

- H6** *The more questions a tutor/student asks, the more likely a tutorial dialogue will be successful.*
Previous research demonstrated that questioning is an essential method for tutors to help students build up their understanding and promote effective learning [20, 44, 50]. Likewise, questions asked by a student represent the student's activeness in learning what is unknown to her at the moment and are generally viewed as positively related to her learning performance [43, 45, 46].
- H7** *The more positive sentiment conveyed through the utterances sent by a student/tutor, the more likely a tutorial dialogue will be successful.*
[9, 51] suggested that students' sentiment expressed via forum posts in a MOOC is correlated with the retention rate of the course. This led us to postulate that the success of a tutoring session could be revealed by students' sentiment conveyed in the dialogue utterances. Also, the positive sentiment contained in tutors' utterances, e.g., those used to encourage students, can be indicative of the success of a tutoring session.
- H8** *The more prior tutorial dialogues a student/tutor has, the more likely the current dialogue will be successful.*
On the one hand, the number of prior tutorial dialogues that tutors have can be used to estimate their prior tutoring experience, which is generally believed to have a positive effect on students' learning outcome [48]. On the other hand, if a student has multiple sessions before the current session, this may imply that (i) the student is familiar in using the tutoring platform; and (ii) the tutoring platform has gained the trust of the student by providing satisfactory learning experiences; thus the student repeatedly returns to the platform and uses the service.

3.3 Hypotheses Testing

To test the formulated hypotheses, we first classified tutorial dialogues receiving ratings of 4 or 5 from students as the *Success* group and those of ratings of 1 or 2 as the *Failure* group. Then, we defined a set of metrics to describe the factors investigated in each hypothesis and compared the two groups with Mann-Whitney test on the relevant metrics to test our hypotheses.

For **H1**, we quantified the efforts of tutors/students made in a tutoring session from three perspectives:

- M1 Session duration:** the duration of a tutoring session;
M2 # Utterances: the number of utterances made by a tutor/student;
M3 # Words: the number of words contained in the utterances made by a tutor/student;

To investigate **H2**, we considered four metrics to measure utterance informativeness:

- M4 # Unique words:** the number of unique words contained in utterances sent by a tutor/student;
M5 # Unique concepts: the number of concepts contained in utterances introduced by a tutor/student;
M6 % New words: the fraction of unique words sent by a tutor/student for the first time (so-called *new words*);
M7 % New concepts: the fraction of unique concepts introduced by a tutor/student for the first time (so-called *new concepts*);

Counting the number of unique words (**M4**) was one indicator to measure the informativeness of utterances. Besides, given that both tutors and students often use concepts during the conversational problem-solving process (as shown in Figure 1 where *triangle* was mentioned by both the tutor and the student), and such concepts often bring new information, we also calculated the number of unique concepts (**M5**) to measure the utterance informativeness. As concepts typically appear as nouns, we extracted the nouns contained in an utterance and used them as proxies to capture the mentioned concepts. For this, we use NLTK⁴ to extract nouns from utterances. In addition, we also defined **M6** and **M7** to measure the extent to which the new words/concepts were spoken by tutors/students, as indicators to distinguish the main contributor in bringing new information in a dialogue.

We tested **H3** from two angles:

- M8 Wait time:** the amount of time between a student initialized a request for help and the student was connected to a tutor;
M9 Avg. response time: the average amount of time that a student needed to wait before receiving a reply from a tutor after the student sent an utterance;

To investigate **H4**, we defined the following metric:

- M10 Entrainment:** the score describing the level of entrainment between the tutor utterances and the student utterances;

Inspired by [4], we calculated **M10** as the similarity between the distribution of respective words used by tutors and students. Specifically, we first needed to decide the set of considered words used to calculate entrainment score. [34] suggested that function words (i.e., frequent words like *is*, *do*, *can*) and punctuation marks are important for measuring the degree to which people align with each other in successful dialogues. Therefore, we took all of the words appearing in dialogues into account for calculating **M10** (denoted as *Entrainment (All)*). In addition, as indicated before, both tutors and students often use concepts during the tutoring process and we hypothesized that the entrainment between such concepts was of particular importance to indicate whether a dialogue would be successful or not. Therefore, we also calculated **M10** by only considering concepts (denoted as *Entrainment (Concepts)*). Similar to **H2**, we extracted nouns in utterances and regarded them as the concepts mentioned by tutors and students. With the set of considered words defined, we counted the occurrence of

⁴<https://www.nltk.org>

each word for the utterances made by a tutor/student in a dialogue, respectively, which were represented as two vectors (one for the tutor and the other for the student). Then, we measured the similarity of the two vectors by computing their cosine similarity [22], which served to describe how close the tutor and the student were in terms of the vocabulary they used in a dialogue and thus to indicate to what extent they coordinated the words to each other.

To test **H5-8**, we respectively defined the following metrics:

M11 Complexity: the average complexity of utterances sent by a tutor/student;

M12 # questions: the number of questions asked by a tutor/student;

M13 Sentiment: the overall sentiment polarity scores of utterances sent by a tutor/student;

M14 Platform experience: the number of tutorial dialogues that a tutor/student has prior to the current one;

Specifically, we measured the complexity (**M11**) of an utterance by calculating its Flesch readability score [12], which specify to what extent a piece of text is readable to people by returning a score between [0, 100]. A piece of text with a higher Flesch readability score indicates it is easier to understand. Given that questions often ended with a question mark, we, therefore, computed **M12** as the number of sentences ending with a question mark in the utterances made by a tutor/student. For **M13**, we again use *NLTK* to determine the sentiment polarity score for each utterance. The returned score was of range $(-1, 1)$ with -1 being very negative and 1 being very positive. Then, the values of all utterances sent by a tutor/student were summed up as the overall score of the tutor/student in a dialogue, and the scores of all dialogues in a group were averaged as the final score for the group.

3.4 Tutoring Success Prediction

We aimed to predict whether a tutoring session would be successful or not based on the transcript of the tutorial dialogue, which could be regarded as a binary classification problem. Previous research indicated that there are various techniques that can be used for binary classification problems, such as logistic regression, decision trees, random forests, support vector machines, and neural networks. Gradient Tree Boosting (GTB) [11, 18] is a machine learning technique which can be used for both regression and classification problems. Similar to random forests, GTB is based on the belief that multiple predictors aiming to predict the same target variable will do a better job than any single predictor alone. Therefore, GTB constructs a set of predictors (i.e., decision trees), which are typically trained with a random sub-sample of the data (thus each predictor is slightly different from the others) and the predictions of all predictors are taken into account to give a final prediction. In random forests, the predictors are built independently and the predictions are combined by using techniques like weighted average and majority vote. However, in GTB, the predictors are built sequentially in which the later predictors can learn from mistakes committed by previous predictors

and thus reduce prediction errors. This usually takes less time to reach close to actual predictions. Previous research has demonstrated that GTB is one of the most robust machine learning approaches and can deal with various types of feature data and has reliable predictive power when dealing with unbalanced data (as in our case) [10]. Therefore, we select GTB over other approaches for our prediction task.

We used all of the metrics described in Section 3.3, i.e., M1-14, as features for the Gradient Tree Boosting model. Note that we calculated M2-7, M11-14 for both tutors and students, respectively. M10 was calculated by taking all of the words as well as only the concepts into consideration. In addition, as a common practice in solving text classification problems, we extracted *N-grams* features, i.e., unigrams, bigrams, and trigrams, from the dialogue transcripts. Prior to the N-grams extraction, we preprocessed the dialogue transcripts by removing stopwords (e.g., *can*, *a*, *be*, *is*, *are*), which are of high frequency but seldom carry useful information for classification purposes. To avoid overfitting, we only took the top 100 most frequent unigrams, bigrams, and trigrams into consideration. In total, we designed 325 features.

To set up the experiment, we randomly sampled 80% of the data as the *training* dataset, and the remaining 20% as the *validation* and *testing* datasets (10% for each). To demonstrate the effectiveness of GTB in predicting tutoring success, we selected random forests as the baseline method for comparison. We implemented random forests as well as GTB by using the machine learning library *scikit-learn*⁵ for Python. The parameters for both random forests and GTB were optimized through grid search on the validation dataset, and then we evaluated the models' performance on the testing dataset. In line with previous works on classification problems, especially those dealing with imbalanced data, we adopted three representative metrics for evaluation, i.e., Area Under the Curve (AUC), F1 score, and Cohen's kappa coefficient (Cohen's κ) [23].

In particular, the design of our experiments was guided by the following three questions:

- Q1** How does GTB perform in predicting the success of a tutorial dialogue?
- Q2** How much data is needed to successfully predict tutoring success?
- Q3** Which of the designed features are of particular importance for the prediction performance?

To our knowledge, there have been few works attempting to predict the success of a tutorial dialogue with a large-scale dataset and our work has contributed to this by enabling a better understanding of this problem. By investigating **Q1**, we expected to examine the capability of GTB, which is regarded as a state-of-the-art machine learning technique, in solving this particular prediction task. Previous works demonstrated that the earlier a student is identified as being at risk, the more help a tutor can offer to help the student continue to learn. Similarly, the earlier an unsuccessful tu-

⁵<https://scikit-learn.org/>

toring session can be identified, the more effective intervention can be provided to the student by a tutor. Therefore, by investigating **Q2**, we expected to identify how early an unsuccessful tutoring session can be identified and to shed light on the practicability of using GTB to assist tutors during their interaction with students. Lastly, by answering **Q3**, we expected to examine the contributions made by each type of features for the prediction performance.

4. RESULTS

In this section, we describe the experimental results on hypotheses testing as well as tutoring success prediction.

4.1 Results on Hypotheses Testing

For **H1**, we calculated the mean values of M1-3 for all the dialogues contained in the *Failure* and *Success* groups, which are given in Table 2 (so as the other results for H2-8). Based on the results, we observed that the *Success* dialogues were 50% longer than the *Failure* dialogues (31.20 vs. 19.27). In addition, compared to the *Failure* dialogues, both tutors and students had more utterances in the *Success* dialogues. We had similar observations when comparing the number of words sent by tutors/students in the two groups. Therefore, we conclude that H1 was supported.

Table 2: Results on validating the formulated hypotheses. T represents tutors and S represents students. Significant differences (according to Mann-Whitney test) between *Failure* group and *Success* group are marked with ** ($p < 0.001$).

Hypotheses	Metrics	Failure	Success
H1	Session length (mins) **	19.27	31.20
	# Utterances (T) **	28.79	51.46
	# Utterances (S) **	21.32	35.36
	# Words (T) **	315.95	518.21
	# Words (S) **	82.33	146.44
H2	# Unique words (T) **	117.1	157.12
	# Unique words (S) **	47.43	74.52
	# Unique concepts (T) **	102.84	138.43
	# Unique concepts (S) **	41.73	64.34
	# New words (T) **	76.75	74.38
	# New words (S) **	23.25	25.62
	# New concepts (T) **	76.39	74.66
	# New concepts (S) **	23.61	25.34
H3	Wait time	24.09	24.37
	Avg. response time **	32.93	27.89
H4	Alignment (All) **	0.83	0.86
	Alignment (Concepts) **	0.87	0.89
H5	Complexity (T) **	83.93	85.11
	Complexity (S)	100.71	101.26
H6	# Questions (T) **	10.34	17.14
	# Questions (S) **	1.85	4.05
H7	Sentiment (T) **	4.58	9.38
	Sentiment (S) **	1.54	3.32
H8	Experience (T)	160.66	162.56
	Experience (S) **	9.11	12.67

To validate **H2**, we computed M4-7 over all the utterances sent by a tutor(student) in a dialogue and summed up the values to measure how informative the tutor(student) was in the dialogue. Then, the metric values of all dialogues contained in a group were averaged as the final value. We found that both tutors and students used a higher number of unique words as well as unique concepts (M4-5) in the *Success* group than those in the *Failure* group. In particular, students of *Success* group used about 50% more unique words and concepts than their peers in the *Failure* group. These results suggest that, in order to solve problems, both tutors and students in the *Success* group introduced a greater variety of words during tutoring process and thus were more informative. Interestingly, when inspecting the results of M6-7, we found that the *Success* students introduced a larger fraction of new words as well as new concepts compared to the *Failure* students, and correspondingly the *Success* tutors were less active than the *Failure* tutors in bringing new words and concepts to their dialogues. This motivates us to design further experiments to investigate, during the tutoring process, whether tutors should intentionally encourage students to use more new words and concepts to explain problems as well as their thoughts so as to help students solve the problems. To summarize, the observed results indicate that H2 was supported by the analysis of our dataset.

For **H3**, we only observed a significant difference between the two groups in terms of M9. Compared to *Failure* students, *Success* students spent less time (about 5 seconds) in waiting for responses from tutors. Thus, there was some support for H3.

From the reported results of M10, we concluded that **H4** was supported, i.e., the tutors and students were more likely to align with each other in terms of the words they used in the *Success* group than in the *Failure* group. In particular, when only taking concepts into account, we had a slightly higher entrainment score, which implies a higher degree to which tutors and students coordinated concepts than other words in the tutorial dialogues.

By inspecting the results of M11, we discovered that the utterances made by tutors in the *Success* group were slightly less complex than those in the *Failure* group (85.11 vs. 83.93). However, we did not observe a significant difference between the utterances made by students in the two groups. Therefore, **H5** was only supported for tutors.

For **H6**, the results of M12 were in line with our assumption: both tutors and students asked more questions in successful tutoring sessions than those in unsuccessful ones. Particularly, the *Success* students asked more than two times of questions than *Failure* students. Also, it is important to note that, in both groups, tutors asked many more questions than students (about 4~5 times). This is aligned with our previous findings related to the testing of **H1**: tutors tended to make more efforts than students in tutoring sessions.

For **H7**, we noted that the tutors as well as students in the *Success* group displayed a higher level of positive sentiment than those in the *Failure* group. Also, the tutors were more likely to use words of positive sentiment than students in

both groups. Therefore, we concluded H7 was supported.

Lastly, we observed a significant difference on M14 for students, i.e., the platform experience of the *Success* students was significantly higher than that of the *Failure* students. Thus, we concluded that H8 was only supported for students.

4.2 Results on Tutoring Success Prediction

For Q1 described in 3.4, i.e., whether GTB is capable of predicting the success of a tutoring session, we reported the results of GTB as well as the baseline method (random forests) in Rows 1-2 in Table 3. The results indicated that GTB outperformed random forests on all of three evaluation metrics. This demonstrated the effectiveness of GTB for predicting whether a tutoring session will be successful or not. Particularly, GTB attained an improvement of 21% over random forests in terms of Cohen’s κ , though the value was only 0.4323, which implied that the constructed prediction model achieved a *moderate* performance level [28]. This calls for further research effort in developing more effective prediction models for this particular task.

To answer Q2, we trained GTB by using different portions of the dialogue utterances, i.e., the first 20%/40%/60%/80%. The results are reported in Rows 3-6 in Table 3. To our surprise, even using the first 80% of the data to train GTB, the achieved performance was still much inferior to that of using the whole dataset. For instance, the AUC of using the first 80% data was 0.7368, which was 10% lower than that of using the whole dataset. When it comes to Cohen’s κ , the difference became even larger (28% lower). This may imply that the utterances made by tutors and students in the later stage of a tutoring dialogue (especially the last 20%) possibly contained more information for predicting the success of a tutoring session. This motivated us to train the model with the last 20%/40%/60%/80% of the dialogue utterances and reported their performance in Rows 7-10 in Table 3. The results aligned with our assumption. Specifically, solely using the last 20% data already achieved performance that was comparable to that of using the whole dataset. For AUC, it even achieved slightly better performance. This could be explained by the fact that, at the end of successful tutoring sessions, tutors tended to praise students and acknowledge their achievements and students were likely to express their gratitude to the tutors. As a sanity check, we randomly selected 100 successful and unsuccessful dialogues and checked the last 20% utterances in these dialogues. We found that, most of the successful dialogues contained N-grams like (*appreciate*), (*thanks*), (*well, done*), and (*good, job*), which were seldom observed in unsuccessful dialogues. Undoubtedly, these linguistic features served as good indicators for GTB to determine a dialogue’s success.

Lastly, we conducted an ablation study to answer Q3. An ablation study is a frequently-used method to determine to what extent a feature contributes to the performance of a model. Typically, the contribution of a feature is determined by comparing the performance of a model including the feature with that without the feature. The more the performance decreases after removing a feature, the more contribution the feature makes to the model. Instead of identifying the contributions made by each feature we en-

gineered, we were more interested in determining the contributions made by each type of features, i.e., the eight types of feature investigated in 3.3 (*efforts*, *informativeness*, *responsiveness*, *entrainment*, *complexity*, *questions*, *sentiment* and *platform experience*) and the linguistic features (*unigrams*, *bigrams*, *trigrams*). Therefore, we removed each type of feature at a time and reported the model performance in Row 11-20 in Table 3.

We observed that, the top 3 types of feature that made the most contributions to the prediction performance were *unigrams*, *bigrams*, and *efforts*. This was in line with the observation we had when answering Q2, i.e., the linguistic features were predictive in terms of distinguishing successful dialogues from unsuccessful ones.

5. DISCUSSION AND CONCLUSION

Implications for Online Tutors. Through the extensive analysis presented in Section 3.3, we demonstrated that student satisfaction is correlated with a set of dialogue features, which include (i) the efforts invested by tutors/students; (ii) the informativeness of tutor/student utterances; (iii) the readability level of tutor utterances; (iv) tutor responsiveness; (v) the number of questions asked by tutors/students; (vi) the entrainment level of a tutorial dialogue; (vii) the positive sentiment level of tutor/student utterances; and (viii) students’ experience in using the tutoring service. This may shed some light on how to better direct online tutors’ efforts in guiding students. For example, tutors may consider to provide prompt responses, use more words of positive sentiment and suitable readability level, and ask a suitable number of questions to assist students to solve problems. However, it should be noted that the identified dialogue features (as well as the corresponding tutoring implications) may be correlated with each other, e.g., the increased number of utterances might introduce a higher number of questions asked by tutors/students. Further experiments, e.g., online A/B testing, are needed to verify which factors are actually affecting student satisfaction in this context. Also, it is necessary to further investigate whether there are any other factors contributing to the observed correlation. For example, though we observed that students’ experience (measured by the number of tutoring sessions they had before) is associated with their satisfaction, it is still unclear whether this is because of students’ familiarity in using the platform, which enables them to quickly find a tutor and solve a problem, or because of their established loyalty in using the tutoring service. For the former case, it would be beneficial to develop guidelines to help novice students quickly learn how to use the tutoring service. For the latter case, it would be necessary to scrutinize the tutoring sessions that students had before so as to better investigate the elements contributing to students’ established loyalty for the tutoring platform.

Improvement space for satisfaction prediction. Our study demonstrated that Gradient Tree Boosting model is effective in predicting tutoring success with all of the utterances or the utterances from the later period of a tutorial dialogue as input. However, this might be of little value to improve online tutoring service in the real-world setting, i.e., if an unsuccessful dialogue can only be identified (almost) until the end, there is not much a tutor can do to change

Row ID	Method	Data usage	Features	Compared row	AUC	F1	Cohen's κ

20			w/o Trigrams		0.8233 (\uparrow 0.10%)	0.8993 (\downarrow 0.27%)	0.4302 (\downarrow 0.49%)

Table 3: Experimental results on tutoring success prediction. The percentage value within brackets indicates the increased/decreased (denoted by \uparrow/\downarrow , respectively) performance of evaluation metrics, which were computed by taking the results of the compared row as a comparison. The results in bold represent the top 3 decreased performance among Rows 10-20.

the situation. Therefore, more research is needed to build effective satisfaction prediction models, especially with only the utterances close to the beginning of a dialogue as input. Since we only engineered relatively shallow linguistic features (i.e., unigrams, bigrams, trigrams) as input for the prediction model, which made much larger contributions to the prediction performance compared to other types of feature, it is worthwhile to explore more in-depth linguistic features (e.g., word/phrase/sentence embedding [2]) to boost the prediction performance. Also, noteworthy is that all the features we designed as input for Gradient Tree Boosting model is derived from dialogue utterances without considering the sequential nature between them. In the future, it would be useful to explore the suitability of time series models to capture the underlying time-aware interaction patterns between tutors and students for this prediction task. In addition, it is recognized that data imbalance (as in our case) can have a big impact on the classification performance [26]. We posit that techniques used to reduce impacts of data imbalance like SMOTE [7] would probably help in future research on this problem.

ABSTRACT

Spaced repetition is among the most studied learning strategies in the cognitive science literature. It consists in temporally distributing exposure to an information so as to improve long-term memorization. Providing students with an adaptive and personalized distributed practice schedule would benefit more than just a generic scheduler. However, the applicability of such adaptive schedulers seems to be limited to pure memorization, e.g. flashcards or foreign language learning. In this article, we first frame the research problem of optimizing an adaptive and personalized spaced repetition scheduler when memorization concerns the application of underlying multiple skills. To this end, we choose to rely on a student model for inferring knowledge state and memory dynamics on any skill or combination of skills. We argue that no knowledge tracing model takes both memory decay and multiple skill tagging into account for predicting student performance. As a consequence, we propose a new student learning and forgetting model suited to our research problem: DAS3H builds on the additive factor models and includes a representation of the temporal distribution of past practice on the skills involved by an item. In particular, DAS3H allows the learning and forgetting curves to differ from one skill to another. Finally, we provide empirical evidence on three real-world educational datasets that DAS3H outperforms other state-of-the-art EDM models. These results suggest that incorporating both item-skill relationships and forgetting effect improves over student models that consider one or the other.

Keywords

Student modeling, adaptive spacing, memory, knowledge components, q-matrix, optimal scheduling

1. INTRODUCTION

Learners have to manage their studying time wisely: they constantly have to make a trade-off between acquiring new knowledge and reviewing previously encountered learning

material. Considering that learning often involves building on old knowledge (e.g. in mathematics) and that efforts undertaken in studying new concepts may be significant, this issue should not be taken lightly. However, only few school incentive structures encourage long-term retention, making students often favor short-term memorization and poor learning practices [37, 22].

Fortunately, there are simple learning strategies that help students efficiently manage their learning time and improve long-term memory retention at a small cost. Among them, the *spacing* and the *testing* effects have been widely replicated [36, 7] since their discovery in the 19th century. Both of them are recommended by cognitive scientists [24, 46] in order to improve public instruction. The spacing effect states that temporally distributing learning episodes is more beneficial to long-term memory than learning in a single massed study session. The testing effect [35, 5] – also known as *retrieval practice* – basically consists in self-testing after being exposed to new knowledge instead of simply reading the lesson again. This test can take multiple forms: free recall, cued recall, multiple-choice questions, application exercises, and so on. A recent meta-analysis on the testing effect [1] found a strong and positive overall effect size of $g = 0.61$ for testing compared to non-testing reviewing strategies. Another meta-analysis [23] investigated whether learning with retrieval practice could transfer to different contexts and found a medium yet positive overall transfer effect size of $d = 0.40$. Combining both strategies is called *spaced retrieval practice*: temporally distributing tests after a first exposure to knowledge.

Recent research effort has been put on developing adaptive and personalized spacing schedulers for improving long-term retention of flashcards [40, 33, 18]. Compared to non-adaptive schedulers, they show substantial improvement of the learners' retention at immediate and delayed tests [19]. However, and to the best of our knowledge, there is no work on extending these algorithms when knowledge to be remembered concerns the application of underlying skills. Yet, the spacing effect is not limited to vocabulary learning or even pure memorization: it has been successfully applied to the acquisition and generalization of abstract science concepts [44] and to the practice of mathematical skills in a real educational setting [3]. Conversely, most models encountered in knowledge tracing involve multiple skills, but do not model forgetting. The goal of the present article is to start filling this gap by developing a student learning and forgetting

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 29 - 38

model for inferring skills knowledge state and memory dynamics. This model will serve as a basis for the future development of adaptive and personalized skill practice scheduling algorithms for improving learners’ long-term memory.

Our contribution is two-fold. We first frame our research problem for extending the flashcards-based adaptive spacing framework to contexts where memorization concerns the application of underlying skills. In that perspective, students learn and reinforce skill mastery by practicing items involving that skill. We argue that this extension requires new student models to model learning and forgetting processes when multiple skills are involved by a single item. Thus, we also propose a new student model, coined DAS3H, that extends DASH [18, 22] and accounts for memory decay and the benefits of practice when an item can involve multiple knowledge components. Finally, we provide empirical evidence on three publicly available datasets showing that our model outperforms other state-of-the-art student models.

2. RELATED WORK

In this section, we first detail related work on adaptive spacing algorithms before turning to student modeling.

In what follows, we will index students by $s \in \llbracket 1, S \rrbracket$, items (or questions, exercises) by $j \in \llbracket 1, J \rrbracket$, skills or knowledge components (KCs) by $k \in \llbracket 1, K \rrbracket$, and timestamps by $t \in \mathbb{R}^+$ (in days). To be more convenient, we assume that timestamps are encoded as the number of days elapsed since the first interaction with the system. It is sufficient because we only need to know the duration between two interactions. $Y_{s,j,t} \in \{0, 1\}$ gives the binary correctness of student s answering item j at time t . σ is the logistic function: $\forall x \in \mathbb{R}, \sigma(x) = 1/(1 + \exp(-x))$. $KC(\cdot)$ takes as input an item index j and outputs the set of skill indices involved by item j .

Let us quickly detail what we mean by *skill*. In this article, we assimilate skills and knowledge components. Knowledge components are atomistic components of knowledge by which items are tagged. An item may have one or more KCs, and this information is synthesized by a so-called binary q-matrix [41]: $\forall (j, k) \in \llbracket 1, J \rrbracket \times \llbracket 1, K \rrbracket, q_{jk} = \mathbf{1}_{k \in KC(j)}$. We assume that the probability of answering correctly an item j that involves skill k depends on the student’s mastery of skill k ; conversely, we measure skill mastery by the ability of student s to remember skill k and apply it to solve any (possibly unseen) item that involves skill k .

2.1 Adaptive spacing algorithms

Adaptive spacing schedulers leverage the spaced retrieval learning strategy to maximize learning and retention of a set of items. They proceed by sequentially deciding which item to ask the user at any time based on the user’s past study history. Items to memorize are often represented by flashcards, i.e. cards on which one side contains the question (e.g. *When did the Great Fire of London occur?* or *What is the correct translation of “manger” in English?*) and the other side contains the answer.

Early adaptive spacing systems made use of physical flashcards [17] but the advent of computer-assisted instruction made possible the development of electronic flashcards [51],

thus allowing more complex and personalized strategies for optimal reviewing. Nowadays, several adaptive spacing softwares are available to the general public, e.g. Anki¹, SuperMemo², and Mnemosyne³.

Originally, adaptive reviewing systems took decisions based on heuristics and handmade rules [17, 30, 51]. Though maybe effective in practice [20], these early systems lack performance guarantees [40]. Recent research works started to tackle this issue: for instance, Reddy et al. propose a mathematical formalization of the Leitner system and a heuristic approximation used for optimizing the review schedule [32].

A common approach for designing spaced repetition adaptive schedulers consists in modeling human memory statistically and recommending the item whose memory strength is closest to a fixed value θ [22, 18, 20]. Khajah, Lindsey and Mozer found that this simple heuristic is only slightly less efficient than exhaustive policy search in many situations [14]. It has the additional advantage to fit into the notion of “desirable difficulties” coined by Bjork [4]. Pavlik and Anderson [26] use an extended version of ACT-R declarative memory model to build an adaptive scheduler for optimizing item practice (in their case, Japanese-English word pairs) given a limited amount of time. ACT-R is originally capable of predicting item correctness and speed of recall by taking recency and frequency of practice into account. Pavlik and Anderson extend ACT-R to capture the spacing effect as well as item, learner, and item-learner interaction variability. The adaptive scheduler uses the model estimation of memory strength gain at retention test per unit of time to decide when to present each pair of words to a learner.

Other approaches do not rely on any memory model: Reddy, Levine and Dragan formalize this problem as a POMDP (Partially Observable Markov Decision Process) and approximately solve it within a deep reinforcement learning architecture [33]. However, they only test their algorithm on simulated students. A more recent work [40] formalizes the spaced repetition problem with marked temporal point processes and solves a stochastic optimal control problem to optimally schedule spaced review of items. Mettler, Massey and Kellman [19] compare an adaptive spacing scheduler (ARTS) to two fixed spacing conditions. ARTS leverages students’ response times, performance, and number of trials to dynamically compute a priority score for adaptively scheduling item practice. Response time is used as an indicator of retrieval difficulty and thus, learning strength.

Our work can more generally relate to the problem of automatic optimization of teaching sequences. Rafferty et al. formulate this problem as a POMDP planning problem [31]. Whitehill and Movellan build on this work but use a hierarchical control architecture for selecting optimal teaching actions [48]. Lan et al. use contextual bandits to select the best next learning action by using an estimation of the student’s knowledge profile [16]. Many intelligent tutoring systems (ITS) use mastery learning within the Knowledge Tracing [8] framework: making students work on a given

¹<https://apps.ankiweb.net/>

²<https://www.supermemo.com/>

³<https://mnemosyne-proj.org/>

skill until the system infers that they have mastered it.

We can see that the traditional adaptive spacing framework already uses a spaced retrieval practice strategy to optimize the student’s learning time. However, it is not directly adapted to learning and memorization of skills. In this latter case, specific items are the only way to practice one or multiple skills, because we do not have to memorize the content directly. Students who master a skill should be able to generalize to unseen items that also involve that skill. In Section 3, we propose an extension of this original framework in order to apply adaptive spacing algorithms to the memorization of skills.

2.2 Modeling student learning and forgetting

The history of scientific literature on student modeling is particularly rich. In what follows, we focus on the subproblem of modeling student learning and forgetting based on student performance data.

As Vie and Kashima recall [43], two main approaches have been used for modeling student learning and predicting student performance: Knowledge Tracing and Factor Analysis.

Knowledge Tracing [8] models the evolution of a student’s knowledge state over time so as to predict a sequence of answers. The original and still most widespread model of Knowledge Tracing is Bayesian Knowledge Tracing (BKT). It is based on a Hidden Markov Model where the knowledge state of the student is the latent variable and skill mastery is assumed binary. Since its creation, it has been extended to overcome its limits and account for instance for individual differences between students [52]. More recently, Piech et al. replaced the original Hidden Markov Model framework with a Recurrent Neural Network and proposed a new Knowledge Tracing model called Deep Knowledge Tracing (DKT) [29]. Despite a mild controversy concerning the relevance of using deep learning in an educational setting [50], recent works continue to develop this line of research [53, 21].

Contrary to Knowledge Tracing, Factor Analysis does not originally take the order of the observations into account. IRT (Item Response Theory) [42] is the canonical model for Factor Analysis. In its simplest form, IRT reads:

$$\mathbb{P}(Y_{s,j} = 1) = \sigma(\alpha_s - \delta_j)$$

with α_s ability of student s and δ_j difficulty of item j . One of the main assumptions of IRT is that the student ability is static and cannot change over time or with practice. Despite its apparent simplicity, IRT has proven to be a robust and reliable EDM model, even outperforming much more complex architectures such as DKT [49]. IRT can be extended to represent user and item biases with vectors instead of scalars. This model is called MIRT, for Multidimensional Item Response Theory:

$$\mathbb{P}(Y_{s,j} = 1) = \sigma(\langle \alpha_s, \delta_j \rangle + d_j).$$

In this case, α_s and δ_j are d -dimensional vectors, and d_j is a scalar that captures the easiness of item j . $\langle \cdot, \cdot \rangle$ is the usual dot product between two vectors.

More recent works incorporated temporality in Factor Analysis models, by taking practice history into account. For

instance, AFM (Additive Factor Model) [6] models:

$$\mathbb{P}(Y_{s,j} = 1) = \sigma \left(\sum_{k \in KC(j)} \beta_k + \gamma_k a_{s,k} \right)$$

with β_k easiness of skill k and $a_{s,k}$ number of attempts of student s on KC k prior to this attempt. Performance Factor Analysis [27] (PFA) builds on AFM and uses past outcomes of practice instead of simple encounter counts:

$$\mathbb{P}(Y_{s,j} = 1) = \sigma \left(\sum_{k \in KC(j)} \beta_k + \gamma_k c_{s,k} + \rho_k f_{s,k} \right)$$

with $c_{s,k}$ number of correct answers of student s on KC k prior to this attempt and $f_{s,k}$ number of wrong answers of student s on KC k prior to this attempt.

Ekanadham and Karklin take a step further to account for temporality in the IRT model and extend the two-parameter ogive IRT model (2PO model) by modeling the evolution of the student ability as a Wiener process [10]. However, they do not explicitly account for student memory decay.

The recent framework of KTM (Knowledge Tracing Machines) [43] encompasses several EDM models, including IRT, MIRT, AFM, and PFA. KTM’s are based on factorization machines and model the probability of correctness as follows:

$$\mathbb{P}(Y_t = 1) = \sigma \left(\mu + \sum_{i=1}^N w_i x_{t,i} + \sum_{1 \leq i < \ell \leq N} x_{t,i} x_{t,\ell} \langle v_i, v_\ell \rangle \right)$$

where μ is a global bias, N is the number of abstract features, be it item parameters, temporal features, etc., x_t is a sample gathering all features collected at time t : which student answers which item, and information regarding prior attempts, w_i is the bias of feature i and $v_i \in \mathbb{R}^d$ its embedding. The features involved in a sample x_t are typically in sparse number, so this probability can be computed efficiently. In KTM, one can recover several existing EDM models by selecting the appropriate features to consider in the modeling. For instance, if we consider user and item features only, we recover IRT. If we consider the skill features in the q-matrix, and the counter of prior successes and failures at skill level, we recover PFA.

One of the very first works on human memory modeling dates back to 1885 and stems from Ebbinghaus [9]. He models the probability of recall of an item as an exponential function of memory strength and delay since last review. More recently, Settles and Meeder propose an extension of the original exponential forgetting curve model, the half-life regression [38]. They estimate item memory strength as an exponential function of a set of features that contain information on the past practice history and on the item to remember (lexeme tag features, in their case). More sophisticated memory models have also been proposed: for instance ACT-R (Adaptive Character of Thought–Rational) [2] and MCM (Multiscale Context Model) [25].

Walsh et al. [45] offer a comparison of three computational memory models: ACT-R declarative memory model [26],

Predictive Performance Equation (PPE) and a generalization of Search of Associative Memory (SAM). These models differ in how they predict the impact of spacing on subsequent relearning, after a long retention interval. PPE is the only one to predict that spacing may accelerate subsequent relearning (“*spacing accelerated relearning*”) – an effect that was empirically underlined by their experiment. PPE showed also superior fit to experimental data, compared to SAM and ACT-R.

DASH [22, 18] bridges the gap between factor analysis and memory models. DASH stands for Difficulty, Ability, and Student History. Its formulation reads:

$$\mathbb{P}(Y_{s,j,t} = 1) = \sigma(\alpha_s - \delta_j + h_\theta(t_{s,j,1:l}, y_{s,j,1:l-1}))$$

with h_θ a function parameterized by θ (learned by DASH) that summarizes the effect of the $l - 1$ previous attempts where student s reviewed item j ($t_{s,j,1:l-1}$) and the binary outcomes of these attempts ($y_{s,j,1:l-1}$). Their main choice for h_θ is:

$$h_\theta(t_{s,j,1:l}, y_{s,j,1:l-1}) = \sum_{w=0}^{W-1} \theta_{2w+1} \log(1 + c_{s,j,w}) - \theta_{2w+2} \log(1 + a_{s,j,w})$$

with w indexing a set of expanding time windows, $c_{s,j,w}$ is the number of correct outcomes of student s on item j in time window w out of a total of $a_{s,j,w}$ attempts. The time windows w are not disjoint and span increasing time intervals. They allow DASH to account for both learning and forgetting processes. The use of log counts induces diminishing returns of practice inside a given time window and difference of log counts formalizes a power law of practice. The time module h_θ is inspired by ACT-R [2] and MCM [25] memory models.

We can see that Lindsey et al. [18] make use of the additive factor models framework for taking memory decay and the benefits of past practice into account. Their model outperforms IRT and a baseline on their dataset COLT, with an accumulative prediction error metric. To avoid overfitting and making model training easier, they use a hierarchical Bayesian regularization.

To the best of our knowledge, no knowledge tracing model accounts for both multiple skills tagging *and* memory decay. We intend to bridge this gap by extending DASH.

3. FRAMING THE PROBLEM

In our setting, the student learns to master a set of skills by sequentially interacting with an adaptive spacing system. At each iteration, this system selects an item (or exercise, or question) for the student, e.g. *What is $\lim_{x \rightarrow 0} (\sin x)/x$?* This selection is made by optimizing a utility function l that rewards long-term mastery of the set of KCs to learn. Then, the student answers the item and the system uses the correctness of the answer to update its belief concerning the student memory and learning state on the skills involved by the item. Finally, the system provides the student a corrective feedback.

In a nutshell, our present research goal is to maximize mastery and memory of a fixed set of skills among students dur-

ing a given time interval while minimizing the time spent studying.

We rely on the following assumptions:

- information to learn and remember consists in a set of skills⁴ $k \in \llbracket 1, K \rrbracket$;
- skill mastery and memorization of student s at time t is measured by the ability of s to answer an (unseen) item involving that skill, i.e. by their ability to generalize to unseen material;
- students first have access to some theoretical knowledge about skills, but learning happens with retrieval practice;
- items are tagged with one or multiple skills and this information is synthesized inside a binary q-matrix [41];
- students forget: skill mastery decreases as time goes by since last practice of that skill;

Unlike Lindsey et al. [18], we do not assume that items involving skill k are interchangeable: their difficulties, for instance, may differ from one another. Thus, the selection phase is two-fold in that it requires to select the skill to practice *and* the item to present. In theory, there should be at least one item for practicing every skill k ; in practice, one item would be too few, since the student would probably “overfit” on the item. This formalization easily encompasses the flashcards-based adaptive spacing framework: it only requires to associate every item with a distinct skill. This wipes out the need to select an item after the skill.

Different utility functions l can be considered. For instance, Reddy, Levine and Dragan consider both the likelihood of recalling all items and the expected number of items recalled [33]. In our case, the utility function should account for the uncertainty of future items to answer. Indeed, if the goal of the user is to prepare for an exam, the system must take into account that the user will probably have to answer items that they did not train with.

To tackle this problem, like previous work [22, 18], we choose to rely on a student learning and forgetting model. In our case, this model must be able to quantify mastery and memory for any skill or combination of skills. In the next section, we present our main contribution: a new student learning and forgetting model, coined DAS3H.

4. OUR MODEL DAS3H

We now describe our new student learning and forgetting model: DAS3H stands for item Difficulty, student Ability, Skills, and Student Skills practice History, and builds on the DASH model presented in Section 2. Lindsey et al. [18] show that DASH outperforms a hierarchical Bayesian version of IRT on their experimental data, which consist in student-item interactions on a flashcard-based foreign (Spanish) language vocabulary reviewing system. They already talk

⁴These skills may be organized into a graph of prerequisites, but this goes beyond the scope of this article.

about knowledge components, but they use this concept to cluster similar words together (e.g. all conjugations of a verb). Thus, in their setting, an item has exactly one knowledge component; different items can belong to the same knowledge component if they are close enough. As a consequence, their model formulation does not handle multiple skills item tagging, which is common in other disciplines such as in mathematics. Moreover, they assume that the impact of past practice on the probability of correctness does not vary across the skills: indeed, DASH has only two biases per time window w , θ_{2w+1} for past wins and θ_{2w+2} for past attempts. It may be a relevant assumption to prevent overfitting when the number of skills is high, but at the same time it may degrade performance when the set of skills is very diverse and inhomogeneous.

DAS3H extends DASH to items with multiple skills, and allows the influence of past practice on present performance to differ from one skill to another. One could argue that we could aggregate every existing combination of skills into a distinct skill to avoid the burden of handling multiple skills. However, this solution would not be satisfying since the resulting model would for instance not be able to capture item similarities between two items that share all but one skill in common. The use of a representation of multiple skills allows to account for knowledge transfer from one item to another. The item-skill relationships are usually synthesized by a q-matrix and generally require domain experts' labor.

We also leverage the recent Knowledge Tracing Machines framework [43] to enrich the DASH model by embedding the features in d dimensions and model pairwise interactions between those features. So far, KTMs have not been tried with memory features.

In brief, we extend DASH in three ways:

- Extension to handle multiple skills tagging: new temporal module h_θ that also takes the multiple skills into account. The influence of the temporal distribution of past practice and of the outcomes of these previous attempts may differ from one skill to another;
- Estimation of easiness parameters for *each* item j and skill k ;
- Use of KTMs [43] instead of mere logistic regression.

For an embedding dimension of $d = 0$, the quadratic term of KTM is cancelled out and our model DAS3H reads:

$$\mathbb{P}(Y_{s,j,t} = 1) = \sigma(\alpha_s - \delta_j + \sum_{k \in KC(j)} \beta_k + h_\theta(t_{s,j,1:l}, y_{s,j,1:l-1})).$$

Following Lindsey et al. [18], we choose:

$$h_\theta(t_{s,j,1:l}, y_{s,j,1:l-1}) = \sum_{k \in KC(j)} \sum_{w=0}^{W-1} \theta_{k,2w+1} \log(1 + c_{s,k,w}) - \theta_{k,2w+2} \log(1 + a_{s,k,w}).$$

Thus, the probability of correctness of student s on item j at time t depends on their ability α_s , the difficulty of the item δ_j and the sum of the easiness β_k of the skills involved

by item j . It also depends on the temporal distribution and the outcomes of past practice, synthesized by h_θ . In h_θ , w denotes the index of the time window, $c_{s,k,w}$ denotes the amount of times that KC k has been correctly recalled in window w by student s earlier, $a_{s,k,w}$ the amount of times that KC k has been encountered in time window w by student s earlier. Intuitively, h_θ can be seen as a sum of memory strengths, one for each skill involved in item j .

For higher embedding dimensions $d > 0$, in our implementation we use probit as the link function. All features are embedded in d dimensions and their interaction is modeled in a pairwise manner. For a more thorough description of KTMs, see [43]. To implement a model within the KTM framework, one must decide which features to encode in the sparse x vector. In our case, we chose user s , item j , skills $k \in KC(j)$, wins $c_{s,k,w}$ and attempts $a_{s,k,w}$ for each time window w .

Compared to DASH and if we forget about additional parameters induced by the regularization scheme, DAS3H has $(d+1)(K+2W(K-1))$ more feature parameters to estimate. To avoid overfitting, we use additional hierarchical distributional assumptions for the parameters to estimate, as described in the next section.

5. EXPERIMENTS

To evaluate the performance of our model, we compared DAS3H to several state-of-the-art student models on three different educational datasets. These models have been detailed in Section 2.

5.1 Experimental setting

We perform 5-fold cross-validation at the student level for our experiments. This means that the student population is split into 5 disjoint groups and that cross-validation is made on this basis. This evaluation method, also used in [43], has the advantage to show how well an educational data mining model generalizes over previously unseen students.

Following previous work [34, 43] we use hierarchical distributional assumptions when $d > 0$ to help model training and avoid overfitting. More precisely, each feature weight and feature embedding component follows a normal prior distribution $\mathcal{N}(\mu, 1/\lambda)$ where μ and λ follow hyperpriors $\mu \sim \mathcal{N}(0, 1)$ and $\lambda \sim \Gamma(1, 1)$. In their article [18], Lindsey et al. took a similar approach but they assumed that the α_s and the δ_i followed different distributions. Contrary to us, they did not regularize the parameters θ_w associated with the practice history of a student: our situation is different because we have more parameters to estimate than them. We use the same time windows as Lindsey et al. [18]: $\{1/24, 1, 7, 30, +\infty\}$. Time units are expressed in days.

Our models were implemented in Python. Code for replicating our results is freely available on Github⁵. Like Vie and Kashima [43], we used `pywFM`⁶ as wrapper for `libfm`⁷ [34] for models with $d > 0$. We used 300 iterations for the MCMC

⁵<https://github.com/BenoitChoffin/das3h>

⁶<https://github.com/jfloff/pywFM>

⁷<http://libfm.org/>

Gibbs sampler. When $d = 0$, we used the `scikit-learn` [28] implementation of logistic regression with L2 regularization.

We compared DAS3H to DASH, IRT, PFA, and AFM within the KTM framework, for three different embedding dimensions: 0, 5, and 20. When $d > 0$, IRT becomes MIRTb, a variant of MIRT that considers a user bias. We do not compare to DKT, due to the mild controversy over its performance [49, 50]. For DASH, we choose to consider item-specific biases, and not KC-specific biases: in their original setting, Lindsey et al. [18] aggregated items into equivalence classes and trained DASH on this basis. This is not always possible to us because items have in general multiple skill taggings; however, we tested this possibility in Subsection 5.3 but it did not yield better results.

We used three different datasets: ASSISTments 2012-2013 (assist12) [11], Bridge to Algebra 2006-2007 (bridge06) and Algebra I 2005-2006 (algebra05) [39]. The two latter datasets stem from the KDD Cup 2010 EDM Challenge. The main problem for our experiments was that only few datasets that combine both time variables and multiple-KC tagging are publicly available. As a result, only both KDD Cup 2010 datasets have items that involve multiple KCs at the same time. As a further work, we plan to test DAS3H on datasets spanning more diverse knowledge domains and having more fine-grained skill taggings. In ASSISTments 2012-2013, the `problem_id` variable was used for the items and for the KDD Cup datasets, the item variable came from the concatenation of the problem and the step IDs, as recommended by the challenge organizers.

We removed users for whom the number of interactions was less than 10. We also removed interactions with NaN skills, because we feared it would introduce too much noise. For the KDD Cup 2010 datasets, we removed interactions which seemed to be duplicates, i.e. for which the (user, item, timestamp) tuple was duplicated. Finally, we sparsely encoded the features and computed the q-matrices. We detail the dataset characteristics (after preprocessing) in Table 1. The mean skill delay refers to the mean time interval (in days) between two interactions with the same skill, and the mean study period refers to the mean time difference between the last and the first interaction for each student.

5.2 Results

Detailed results can be found in Tables 2, 3 and 4, where mean area under the curve scores (AUC) and mean negative log-likelihood (NLL) are reported for each model and dataset. Accuracy (ACC) is not reported by lack of space. We found that ACC was highly correlated with AUC and NLL; the interested reader can find it on the Github repository containing code for the experiments⁸. Standard deviations over the 5 folds are also reported. We can see that our model DAS3H outperforms all other models on every dataset.

5.3 Discussion

Our experimental results show that DAS3H is able to more accurately model student performance when multiple skill and temporal information is at hand. We hypothesize that

⁸<https://github.com/BenoitChoffin/das3h>

Figure 1: AUC boost when using time windows features instead of regular wins and attempts (all datasets). Higher is better.

this performance gain stems from a more complex temporal modeling of the influence of past practice of skills on current performance.

The impact of the multidimensional embeddings and the pairwise interactions seems to be very small yet unclear, and should be further investigated. An embedding dimension of $d = 20$ is systematically worse or among the worst for DAS3H on every dataset, but with a smaller $d = 5$, the performance is sometimes better than with $d = 0$. An intermediate embedding dimension could be preferable, but our results confirm those of Vie and Kashima [43]: the role of the dimension d seems to be limited.

In order to make more sense of our results, we wanted to know what made DAS3H more predictive than its counterparts. Our hypothesis was that taking the past temporal distribution of practice as well as the outcome of previous encounters with skills allowed the model to capture more complex phenomena than just simple practice, such as forgetting. To test this hypothesis, we performed some ablation tests. We empirically evaluated the difference in terms of AUC on our datasets when time windows features were used instead of regular features for wins and attempts. For each dataset, we compared the mean AUC score of the original DAS3H model with a similar model for which the time windows wins and attempts features were replaced with regular wins and fails counts. Thus, the time module h_θ was replaced with $\sum_{k \in KC(j)} \gamma_k c_{s,k} + \rho_k f_{s,k}$ like in PFA. Since wins, fails and attempts are collinear, it does not matter to replace “wins and attempts” with “wins and fails”. The results are plotted in Figure 1. Mean and standard deviations over 5 folds are reported. We chose an embedding dimension $d = 0$ since it was in general the best on the previous experiments. We observe that using time window features consistently boosts the AUC of the model.

We also wanted to know if assuming that skill practice benefits should differ from one skill to another was a useful assumption. Thus, we compared our original DAS3H formulation to a different version, closer to the DASH formula-

Dataset	Users	Items	Skills	Interactions	Mean correctness	Skills per item	Mean skill delay	Mean study period

tion, in which all skills share the same parameters θ_{2w+1} and θ_{2w+2} inside a given time window w . We refer to this version of DAS3H as DAS3H_{1p}. The results are given in Table 5. They show that using different parameters for different skills in h_θ increases AUC performance. The AUC gain varies between +0.03 and +0.04. This suggests that some skills have significantly different learning and forgetting curves.

One could argue also that this comparison between DAS3H and DASH is not totally accurate. In their papers, Lindsey et al. cluster similar items together to form disjoint knowledge components. This is not possible to perform directly for both KDD Cup datasets since some items have been tagged with multiple skills. Nevertheless, the ASSISTments 2012-2013 dataset has only single-KC items. To evaluate whether considering the temporal distribution and the outcomes of past practice on the KCs (DASH [KC]) or on the items (DASH [items]) would be better, we compared these two DASH formulations on ASSISTments 2012-2013. Detailed results can be found in Table 6. We see that DASH [items] and DASH [KC] have comparable performance.

Finally, let us illustrate the results of DAS3H by taking two examples of KCs of Algebra I 2005-2006, one for which the estimated forgetting curve slope is steep, the other one for which it is more flat. As a proxy for the forgetting curve slope, we computed the difference of correctness probabilities when a “win” (i.e. a correct outcome when answering an item involving a skill) left a single time window. This difference was computed for every skill, for every couple of time

windows, and for every fold. The differences were then averaged over the 5 folds and over the different time windows, yielding for every skill the probability of correctness average decrease when a win leaves a single time window. One of the skills for which memory decays slowly concerns shading an area for which a given value is inferior to a threshold: in average and everything else being equal, the probability of correctness for an item involving this skill decreases by 1.15% when a single “win” leaves a time window. Such a skill is indeed not difficult for a student to master with a few periodic reviews. On the contrary, the skill concerning the application of exponents is more difficult to remember as time goes by: for this KC, the correctness probability decreases by 2.74% when a win leaves a time window. This is more than the double of the previous amount and is consistent with the description of the KC.

In brief, we saw in this section that DAS3H outperforms the other EDM models to which we compared it – including DASH. Using time window features instead of regular skill wins and attempts counts and estimating different parameters for different skills significantly boosts performance. Considering that DAS3H outperforms its ablated counterparts and DASH, these results suggest that including both item-skill relationships and forgetting effect improves over models that consider one or the other. Using multidimensional embeddings, however, did not seem to provide richer feature representations, contrary to our expectations.

Besides its performance, DAS3H has the advantage to be suited to the adaptive skill practice scheduling problem we described in Section 3. Indeed, it encapsulates an estimation of the current mastery of any skill and combination of skills for student s . It can also be used to infer its future evolution and thus, be leveraged to adaptively optimize a personalized skill practice schedule.

6. CONCLUSION AND FUTURE WORK

In this article, we first formulated a research framework for addressing the problem of optimizing human long-term memory of skills. More precisely, the knowledge to be remembered here is *applicative*: we intend to maximize the period during which a human learner will be able to leverage their retention of a skill they practiced to answer an item involving this skill. This framework assumes multiple skills tagging and is adapted to the more common flashcards-based adaptive review schedulers.

We take a student modeling approach to start addressing this issue. As a first step towards an efficient skill practice scheduler for optimizing human long-term memory, we thus propose a new student learning and forgetting model coined DAS3H which extends the DASH model proposed by Lindsey et al. [18]. Contrary to DASH, DAS3H allows each item to depend on an arbitrary number of knowledge components. Moreover, a bias for each skill temporal feature is estimated, whereas DASH assumed that item practice memory decayed at the same rate for every item. Finally, DAS3H is based on the recent Knowledge Tracing Machines model [43] because feature embeddings and pairwise interactions between variables could provide richer models. To the best of our knowledge, KTMs have never been used with memory features so far. Finally, we showed that DAS3H outperforms several state-of-the-art EDM models on three real-world educational datasets that include information on timestamps and KCs. We showed that adding time windows features and assuming different learning and forgetting curves for different skills significantly boosts AUC performance.

This work could be extended in different ways. First, the additive form of our model makes it compensatory. In other terms, if an item j involves two skills k_1 and k_2 , a student could compensate a small practice in k_1 by increasing their practice in k_2 . This is the so-called “explaining away” issue [47]. Using other non-affine models [15] could be relevant. Following Lindsey et al. [18], we used 5 time windows for DAS3H during our experiments: $\{1/24, 1, 7, 30, +\infty\}$. Future work could investigate the impact of alternative sets of time windows – for instance, with more fine-grained time scales. However, one should pay attention not to add too many parameters to estimate.

Future work should also compare DAS3H and DASH to additional student models. For instance, R-PFA [12] (Recent-Performance Factor Analysis) and PFA-decay [13] extend and outperform PFA by leveraging a representation of past practice that puts more weight on more recent interactions. However, they do not explicitly take the temporal distribution of past practice to predict future student performance. Other memory models, such as ACT-R [26] or MCM [25] could also be tested against DAS3H. Latency, or speed of recall, can serve as a proxy of retrieval difficulty and memory strength [19]. It would be interesting to test whether incorporating this information inside DAS3H would result in better model performance.

In a real-world setting, items generally involve multiple skills at the same time. In such a situation, how should one select the next item to recommend a user so as to maximize their long-term memory? The main issue here is that we want to anchor skills in their memory, not specific items. We could think of a two-step recommendation strategy: first, select-

ing the skill k^* whose recall probability is closest to a given threshold (this strategy is consistent with the cognitive psychology literature, as Lindsey et al. recall [18]) and second, selecting an item among the pool of items that involve this skill. However, it could be impossible to find an item that involves *only* this skill k^* . Also, precocious skill reactivations can have a harmful impact on long-term memory [7]. Thus, a strategy could be to compute a score (weighted according to the recall probability of each individual skill) for each skill combination in the q-matrix and to choose the combination for which the score is optimized.

Finally, we tested our model on three real-world educational datasets collected from automatic teaching systems on mathematical knowledge. To experiment with our model, we were indeed constrained in our choice of datasets, since few publicly available of them provide both information on the timestamps and the skills of the interactions. As further work, we intend to test our model on other datasets, from more diverse origins and concerning different knowledge domains. Collecting large, fine-grained and detailed educational datasets concerning diverse disciplines and making them publicly available would more generally allow EDM researchers to test richer models.

Acknowledgements

We would like to warmly thank Pr. Mozer from Univ. of Colorado, Boulder for providing useful details on their papers [22, 18] and allowing us to access the data of their experiment, and to Alice Latimier (LSCP, Paris) for her crucial comments concerning the cognitive science part. This work was funded by Caisse des Dépôts et Consignations, e-Fran program.

ABSTRACT

Recent years have seen a growing interest in block-based programming environments for computer science education. While these environments hold significant potential for novice programmers, they lack the adaptive support necessary to accommodate students exhibiting a wide range of initial capabilities and dispositions toward computing. A promising approach to addressing this problem is introducing adaptive feedback. This work investigates a key capability for adaptive support: training student models that predict student success in block-based programming activities for novice programmers. The predictive student models utilize four categories of features: prior performance, hint usage, activity progress, and interface interaction. In addition to evaluating the accuracy of these models for multiple block-based programming activities, we also investigate how quickly the models converge to accurate prediction, and we evaluate the additive value of each of the four categories of features. Results show that the predictive models are able to predict whether a student will successfully complete an exercise with high accuracy, as well as converge on this prediction early in the sequence of student interactions.

Keywords

Block-Based Programming, Student Performance Prediction, Predictive Student Models

1. INTRODUCTION

A central thrust of computer science education research in recent years has been improving the recruitment and retention of students into computing-related fields of study [2]. Yet, many undergraduate students face challenges in introductory

programming courses [36], which have been found to be particularly difficult for novice learners [4]. Block-based programming languages are a promising approach to supporting novices because they reduce the need to focus on syntax, thereby reducing cognitive load and encouraging novices to attempt more complex implementations [40]. In contrast to text-based programming languages, students using block-based programming languages have been shown to spend proportionally more time on productive coding [24]. Further, some aspects of block-based code representations, such as the nesting of blocks and the closer alignment with natural language expression, can help students better understand programming concepts [37]. However, despite their benefits, block-based programming environments have typically provided limited support to students, which places a significant burden on students, as well as their instructors and teaching assistants who have limited availability.

Adaptive learning environments have had success in a broad range of subject matters [19, 20, 32]. They also offer a promising vehicle for addressing the complexity of scaffolding and assessing students' programming activities [3, 6, 8, 15]. A key feature of adaptive learning environments is their ability to leverage student models that assess knowledge and skills from observed learning activities and support learning based on the estimated competency levels in real time.

In this paper, we introduce predictive student models that generate a series of predictions of student success on block-based programming activities. As students complete programming activities, predictive student models can predict student performance, thereby enabling adaptive learning environments to make informed decisions on when to proactively provide support and scaffolding to struggling students. This paper presents predictive student models for block-based programming activities that were trained on over 200 undergraduate students' interactions with a block-based programming environment in an introductory engineering course. The models utilized four categories of student programming behavior: *prior performance*, *hint usage*, *activity progress*, and *interface interaction*. The trained models accurately predict student performance on future programming activities. Analyses of the feature sets reveal prior performance to be the most predictive feature early in the

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 39 - 48

programming exercises, with other features providing more predictive power as the exercises progress.

This paper is structured as follows. Section 2 discusses related work on analyzing student block-based programs and predicting student coding performance. Section 3 describes PRIME, the block-based programming environment that was used to collect the dataset of students’ construction of block-based programs. Section 4 presents the early prediction student modeling framework, as well as an evaluation of the effectiveness of the models, and Section 5 provides a discussion of the results and design implications.

2. RELATED WORK

Hint generation for block-based programming has been the subject of considerable attention. Given the vast solution spaces of programming exercises, data-driven methods of hint generation have been explored extensively. For example, hint generation for Python tutoring [28] as well as comparing the quality of generated hints to expert hints in a block-based programming environment [25] have both shown promise. However, even with high-quality hints, student performance can nevertheless suffer as a result of poor help-seeking behavior, which is prevalent among students who are most in need of assistance [1]. Approaches to hint generation need to address “gaming the system” behaviors, in which students request multiple levels of hints until they receive a “bottom-out” hint [23] providing the answer to the activity. A potential solution is to design a proactive hint generation framework that can monitor students’ progress and deliver proactive support when necessary [5, 12]. The work presented in this paper seeks to enable such proactive feedback by creating predictive models capable of accurately detecting struggling students and doing so as early as possible.

Student modeling in programming environments has largely focused on constructing granular models of student domain knowledge. These approaches seek to apply modeling techniques such as Bayesian Knowledge Tracing [7] to programming exercises, mapping exercises to individual knowledge components to identify which concepts students are struggling with [27], and to enable mastery learning [9, 18]. Related work has sought to leverage large datasets and deep neural architectures to analyze student behaviors and identify struggling students as they complete open-ended programming activities [35]. This work builds on these inner-loop student models by incorporating new features such as prior performance and hint usage to predict student performance.

In addition to work on programming environments, examining student behaviors in open-ended environments has shown promise. For example, Sabourin et al. utilized dynamic Bayesian networks to create early prediction models of student learning in a game-based learning environment [31]. Min et al. used deep-learning techniques and multimodal datasets to recognize student goals in an open-ended game-based learning environment [21, 22]. Others have used textbook annotations to create early prediction models of student learning [38], clustering techniques for early prediction of students interacting in an open-ended exploratory simulation environment [11, 16], and fine-grained analysis of game-based learning behaviors to predict student quitting (or dropout) early [17].

3. METHODS

In this work, we investigate college student interactions with a block-based programming environment using features that capture system-level interactions, prior student data, and programming progress. We first describe the learning environment, the coding activities, and interface design, followed by the study with college students and the coding problem-solving dataset collected for training and analysis.

3.1 PRIME Environment

PRIME is an adaptive learning environment designed to support novices in learning computer science concepts through block-based programming. Students can use PRIME both during class time as well as for lab and homework assignments.

3.1.1 Task Progression Design

The curriculum for PRIME was informed by a review of the syllabi for introductory programming courses from the fifty top-rated undergraduate computer science programs in the US [33]. From this review, we identified the set of topics that are typically covered in the first five units of courses, as well as the order in which they are covered: 1) *Input/Output, Variables, and Loops*, 2) *Functions, Parameters, and Return Values*, 3) *Conditional Execution*, 4) *String Manipulation and Basic Data Structures*, and 5) *Search and Sort Algorithms*. The work presented in this paper focuses on Units 1-3 (Table 1).

Table 1. Computer science curricular coverage.

Unit	Topics
1	PRIME environment tutorial, Input/Output, Numeric data types, Expressions (math), Variables, Iteration (definite)
2	Abstraction, Functions (methods), Parameters, Return Values
3	Boolean data types, Conditionals, Iteration (indefinite), Debugging

Each unit of PRIME is typically covered in a week and consists of multiple sequential activities. Units 1 and 2 consist of seven activities each, with Unit 3 consisting of six activities. Within each unit, activities progressively build upon concepts and require students to build more complex programs to solve increasingly challenging problems.

3.1.2 Interface Design

To support the translation of block-based programs into their text-based equivalents (e.g., Python), PRIME uses Google’s Blockly framework [13] (Figure 1). The primary user interface provides a *Program* panel, a *Console* panel, a *Feedback* panel, and an *Instructions* panel. The *Program* panel consists of a visual coding widget with the block-based coding workspace and toolbox of available blocks.

The default workspace is augmented with a “Start” block, which serves a purpose analogous to the “main” function or method in other programming languages. The toolbox varies for each task, gradually adding more blocks as students complete tasks and are introduced to new topics. This approach is based on prior work indicating that introducing new blocks only as needed may reduce extraneous cognitive

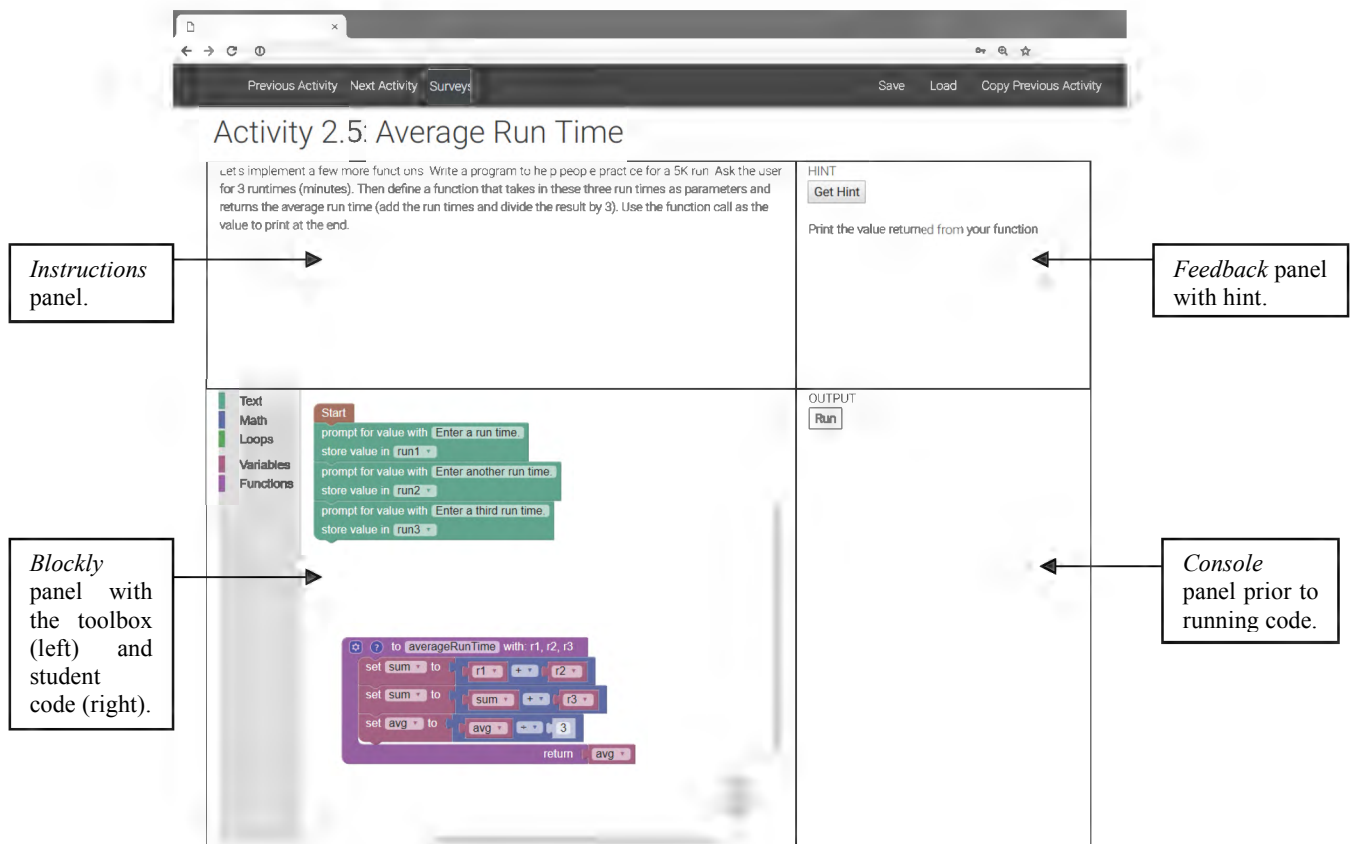

Figure 1. Screenshot of PRIME environment.

load [26] and increase interface usability for novice learners [29].

The *Console* panel contains a “Run” button and shows the output generated from running the program. An input field also appears in this panel if a program prompts the user for input. Finally, the *Instructions* panel contains step-by-step instructions for a given task. This type of instruction format is common for adaptive learning environments [10], though it is rarely found in block-based programming environments. In addition to navigation buttons, this panel also contains positive feedback and links to the next task when a student has successfully completed the current task. Task completeness is checked every time students run their programs and is based primarily on a set of exemplar cases for each activity. Additionally, some activities also check for the presence/absence of certain blocks to ensure an appropriate solution was submitted.

The *Feedback* panel contains the “Get Hint” button, allowing students to request textual hints. Hints are suggestions for minor changes to the program that direct students toward the solution. Hints check various aspects of the student code, including the presence or absence of certain blocks, structural features such as whether code is connected to the “Start” block, and the content of the parameters and fields of certain blocks.

Multiple hints were authored for each activity ($M = 5.40$, $SD = 2.76$) based on common errors identified from prior data collections and pilot testing. The maximum number of hints in an activity is 12, and the minimum authored is 2. An example

of a hint is, “Instead of numbers, you can put other value blocks (like variables) inside the math operation block.” Hints were cast at a sufficiently abstract level that they do not directly provide the solution to an activity but rather nudge students in the right direction. These nudges are designed to assist the student to consider block creations, deletions, or moves that may be advantageous.

Hints are delivered to students in the text panel if they click on the “Get Hint” button in the *Feedback* panel. If no new hints are available, then the button is disabled and cannot be pressed. If there is an available hint different than the one currently displayed, then pressing the button will display that hint. A set of test cases is used to determine which hint is given to the student at a specific point for each activity. The number of test cases passed determines both the specific hint to provide to the student as well as generating the “Next Step” prompt that students receive when completing an intermediate portion of the activity. After requesting a hint, if the student makes changes to satisfy the conditions of the displayed hint, the text of the hint converts to a strikethrough font, visually indicating its status to the student.

3.2 Study Design

Student programming interactions were collected in a study conducted at a large university in the southeastern United States. Participants were students enrolled in two sections of an online introductory course required for all engineering majors. The study sample consisted of 248 students, 222 of which attempted at least one activity.

The average age of the participants was 18, with 31.5% of the group being female. The racial makeup was 75.8% White, 12.9% Asian, 3.2% African American, and 1.2% Hispanic or Latino. The primary major reported was Non-CS Engineering (90.3%), with 6.9% reporting as Computer Science majors and the remaining either Undecided, Math, or Agricultural Science. Of the 222 students, 17.3% reported having prior experience with block-based programming. Of the 222 students who attempted at least one activity, the total number of activities was 2,170 ($M = 9.77$, $SD = 6.24$, Median = 8), and the total number of completed activities was 1,492 ($M = 6.72$, $SD = 4.87$, Median = 4).

3.3 Dataset

The data used in this study was student interaction data collected from students coding with the PRIME block-based programming environment. The data collected for each student consist of actions the student or system took during the course of an attempted activity. For example, the system logs when students perform actions such as requesting a hint, moving a block, creating a block, and other interactions. When a student performs actions relating to a specific block, the system creates an identification number associated with each block to allow easier tracking of specific blocks that the student creates.

As the goal of this work is to predict successful coding activity completion, the activities used for analysis were selected as those with completion rates between 30-70% (i.e., a 70% threshold for the incompleteness/completion rate). Very high completion rates were seen in early activities geared for mastery-oriented introduction to block-based programming. As the activities become more difficult and once the student has been acquainted with the system, the completion rates drop slightly. At the other end of the spectrum, later activities did not have sufficient student attempts for a predictive model to be trained. We therefore focused on the middle activities: 5, 6, 7, 10, 11, 12, 13, 14, 15, 16, 17, and 18. A summary of the completion rates for each activity is shown in Table 2.

Table 2. Completion Rates for each Activity

Activity	Completed	Attempted	Success Rate (%)
5	57	177	32.2
6	61	126	48.4
7	38	108	35.2
10	59	92	64.1
11	46	81	56.8
12	45	71	63.4
13	36	67	53.7
14	32	60	53.3
15	34	78	43.6
16	38	59	64.4
17	39	56	69.6
18	37	55	67.3

3.4 Feature Families

We formulate the task of predictive student modeling for students' coding activities as a binary classification task. We

define successful completion of a block-based programming activity as a coding activity that the student completes from start to finish and fulfills each of the activity requirements. Completing an activity will only occur once for each attempt of an activity by a student, and it is important to note that there is no time limit for the completion to occur: a student's interaction with an activity can last from the time they start the activity until the semester ends or until he or she has completed the activity. The input for the predictive models is the number of student-activity attempts where each pair denotes a student attempt on a particular activity. There were a total of 1,966 student-activity attempts in the dataset. This count is calculated as the number of student-activity attempts for which the student had at least 20 system-logged actions within the given activity, where an action is a system-logged interaction where the student clicks within the environment, creates/deletes/moves blocks, or interacts with any of the system components, such as the toolbox or "Save Workspace" button. Thus, the inputs of the predictive models are features derived from each of these student-activity attempts. We define the model input vectors formally with four categories of features: *prior performance*, *hint usage*, *activity progress*, and *interface interaction*. The **prior performance** feature is defined as the percentage of activities that a student has completed out of the total activities he or she has attempted up to that point. This feature only considers the activities listed in Table 2. The **hint usage** feature is the total number of times a student has requested a hint for the activity (i.e., pressed the "Get Hint" button).

The **activity progress** features denote the system analysis of the student's code up to a particular point within the activity. We use two features, *test cases passed* and *checkpoints passed*, to represent the student's progress. These features are calculated by evaluating the student's code with expert-designed test cases. The *test cases passed* feature represents the overall test cases required to complete the activity, and the *checkpoints passed* feature consists of finer-grained test cases within the activity. The *checkpoints passed* feature is used to select which hint to give to the student when a hint is requested. In addition, these intermediate-level test cases are used to drive the "Next Step" prompts that the student sees when making incremental progress required to complete the activity.

The final family of features, **interface interaction**, consists of 12 features: *enter button presses*, *last save loads*, *previous exercise code loads*, *next instruction clicks*, *previous instruction clicks*, *code runs*, *workspace saves*, *workspace changes*, *block creations*, *block deletions*, *block moves*, and *user interface clicks in block-display*. These features are logged by the system over the course of a student's attempt at the activity and represent a finer-grained snapshot of the student's problem-solving interactions.

We also use a temporal feature, *time interval*, to introduce a measurement of the student's dynamic progress. We use this to encode sequential interactions and summarize the time interval-based cumulative counts of all other features. The time interval in this work is defined as the 30 second segment of cumulative features up to that point in time (e.g., interval 1 consists of all features within the first 30 seconds, interval 5 consists of the cumulative features up to the first 2 minutes and 30 seconds). There is variation in the maximal interval for

students within the same activity because certain students may take longer to complete (or not complete) the activity. As an example, one student may have spent 2 minutes and 30 seconds on a particular activity, so he or she will have 5 rows of data, each considering the cumulative counts of each described feature. Each row is then indexed by the corresponding time interval, 1 through 5. Before passing the complete input vector into our predictive models, we perform standardization on each feature at the activity level (i.e., subtracting the mean and dividing by the standard deviation).

4. RESULTS

4.1 Activity Completion Predictions

To account for differences in curricular content across activities, we trained a separate model for each activity. We maintained the same set of hyperparameter values for the predictive model for each activity in order to support better generalization to other tasks and to observe patterns spanning all interactions rather than within individual activities. Due to the nature of this predictive task and the fact that the sequential intervals for a particular student-activity attempt are indirectly dependent on one another when comparing the same student, we utilize leave-one-out cross-validation (LOOCV) at the student-level within each activity to validate results found by the predictive models. To report the most accurate results, we averaged the results from the cross-validation process to account for the fact that the student occurring in the test set each iteration does not account for the total distribution of the input data, thereby increasing variance in the results. This validation process was motivated by the occurrence of successive intervals for a given student-activity attempt being related. For example, a student who attempted a specific activity will have cumulative actions in their first interval that will also be counted in the next interval. LOOCV at the student-level thereby prevents data leakage. We adopt logistic regression for interpretability.

Table 3. Classification performance using logistic regression. The results for the majority class baseline (BL), full feature set (Full), and best performing individual family of features (Ind.) are shown.

Activity	Accuracy			F1	
	BL	Full	Ind.	Full	Ind.
5	0.662	0.719	0.666	0.132	0.006
6	0.668	0.751	0.774	0.491	0.469
7	0.708	0.710	0.639	0.281	0.206
10	0.636	0.757	0.815	0.575	0.555
11	0.583	0.762	0.761	0.566	0.563
12	0.747	0.737	0.729	0.680	0.729
13	0.749	0.714	0.664	0.606	0.604
14	0.695	0.704	0.766	0.599	0.611
15	0.607	0.603	0.599	0.417	0.418
16	0.625	0.718	0.694	0.621	0.618
17	0.700	0.865	0.857	0.698	0.683
18	0.757	0.818	0.916	0.701	0.729

We report two metrics: accuracy and F1 score. As a classification problem, it is important to predict both the majority and minority classes at a high rate. In most cases, activity completion is the majority class, but in some cases, the classes are reversed. This occurs primarily when the activities become more difficult, and thus the incompleteness rate is greater than the completion rate for that activity. In reporting these metrics, we show both the results from the full set of features (i.e., all four feature categories), and we choose the best single family of features as a comparison. In addition to these, we compare the results against a baseline of the majority class consisting of every time interval where students spent time on an activity. The label for each interval is the end outcome (completion/incompletion) during their interaction with that activity.

Table 3 summarizes the cross-validation results of the full feature sets and the best performing family of features against the majority class baseline. Across all the activities, prior performance was the best performing family of features in 7 out of 12 activities, or 58% of the time. Of the five remaining activities, interface interaction served as the best performing family once, activity progress twice, and hint usage twice.

4.2 Feature Analysis

After determining the best performing model for the entire set of features, it is informative to determine which of the features held the greatest predictive value. After training the model, we evaluated the feature coefficients of the trained regression to determine the relative importance of each of the features. Both the magnitude and sign of the coefficients can be used for interpretation in this case, as we can determine which features were positive or negative predictors in this classification.

Table 4. Logistic regression model coefficients using the full feature set.

Feature	Mean	SD	Rank
Prior Performance	1.269	0.889	1
Time Interval	-1.176	1.493	2
Test Cases Passed	0.828	0.327	3
Block Deletion	0.648	1.486	4

Run Code	-0.013	0.896	16
Previous Instruction	0.004	1.022	17

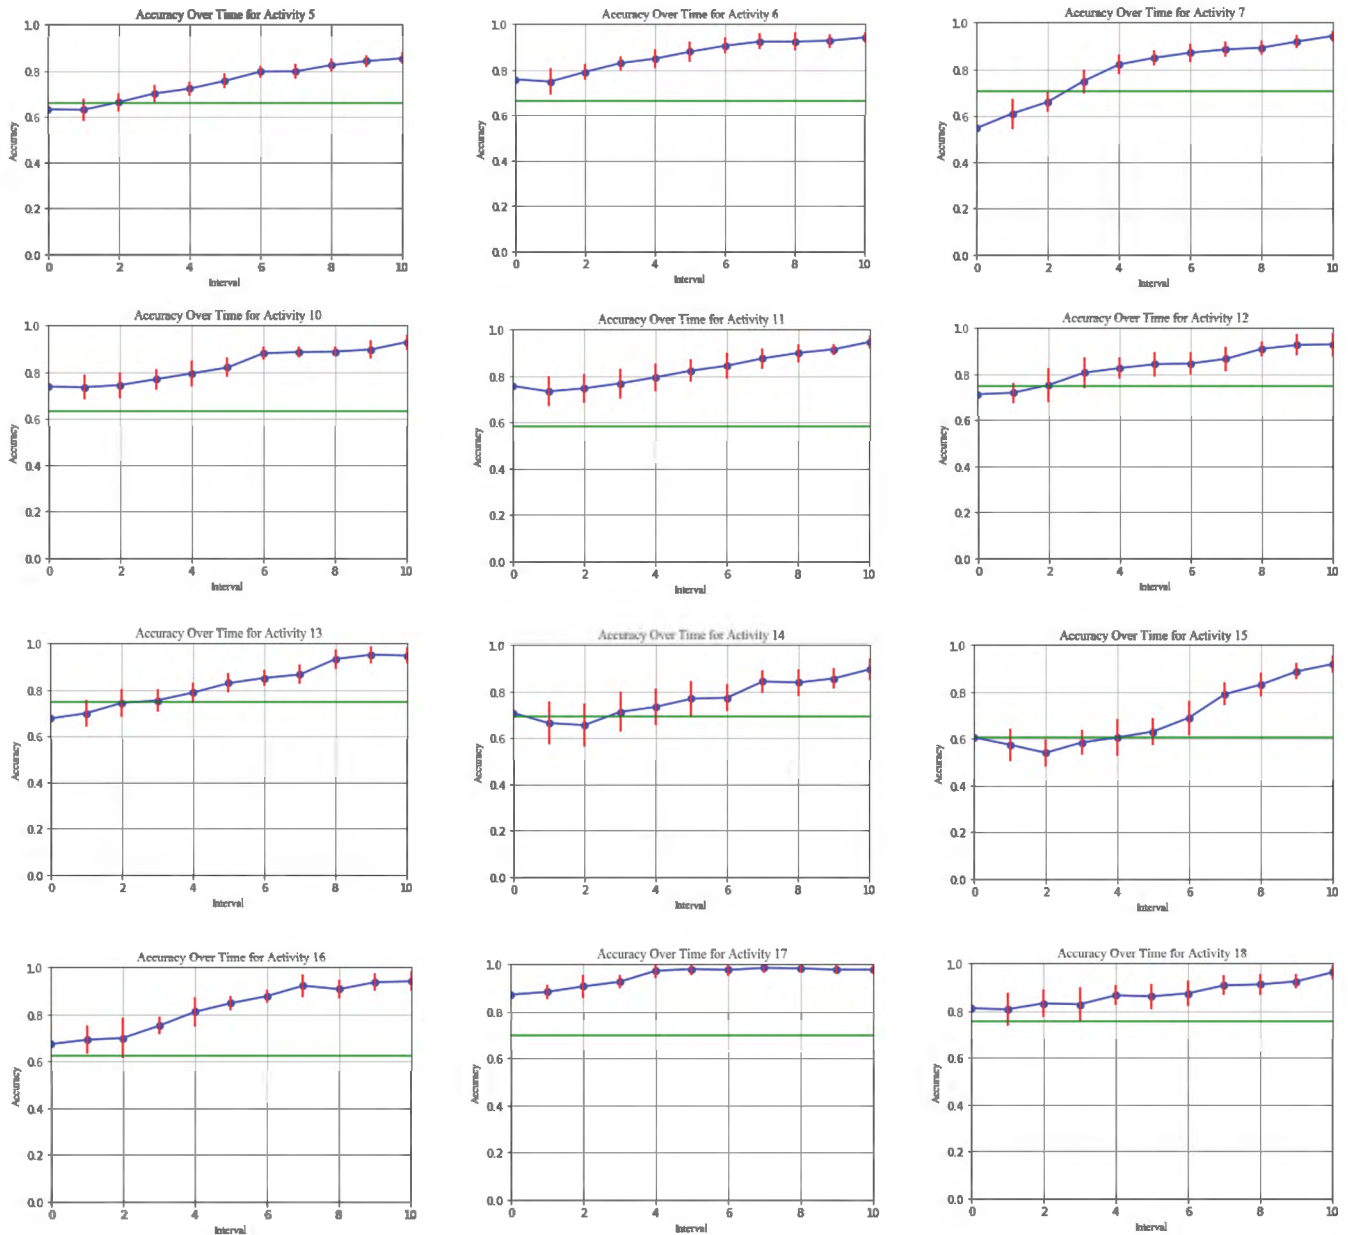

Figure 2. Survival-based analysis of student completion prediction over each interval. The green line represents the baseline for each activity, and the red lines denote the standard deviation of each interval’s average accuracy.

In Table 4, the coefficient results for the full feature set are shown. The four strongest predictors in terms of magnitude were *prior performance*, *time interval*, *test cases passed*, and *block deletion*. Many of the features representing students’ interactions with the block-based environment (e.g., block creations, deletions) provided a strong boost to predictive performance. In addition, features encoding more productivity-based actions, such as *workspace saves* and *checkpoints passed* also provided an improvement to the model. It is worth noting that *time interval* is a strong negative (coefficient direction) predictor, while prior performance was equally as strong of a positive predictor.

4.3 Early Prediction

As a predictive student model observes more student problem-solving actions over time, we would like for its accuracy to improve. A more rapid convergence toward more accurate predictions would mean that an adaptive learning environment could proactively intervene and provide feedback at an earlier stage if the prediction were that the student would not successfully complete an activity. To evaluate this, we performed a survival-based analysis of the predictive models for each interval of each activity. Specifically, we evaluated the performance of our models at each time interval step, where the accuracy at each successive interval includes the students who have already finished interacting with the

activity as correct predictions. The results for this analysis are shown in Figure 2.

For evaluation, we trained the same logistic regression models on each interval for each activity and recorded the number of errors. The accuracy for each interval is then the number of correct predictions divided by the total number of students who attempted that activity (i.e., the total number of samples for the first interval of that activity). Due to the decreasing size of data for each successive interval, we split the data into a 50% train and 50% test set on each interval for each activity, and we took the average performance over 10 randomly generated splits. We then plotted the accuracy over time, noting the standard deviation as the error bars for each interval. We did not perform LOOCV in this analysis because there is at most one interval per student in each activity, so the train/test split will not have data leakage. In other words, splitting the data in half for a train/test split will not have overlapping students in the test set no matter how the split is made.

As noted above, the desired behavior for these predictive models is that accuracy improves over time as the models observe more student problem-solving interaction data. An additional desirable characteristic is that models surpass the baseline at a relatively fast rate. We note that in 8 of the 12 activities, the accuracy of the first interval is at or above that of the baseline (interval-level class majority). For the remaining activities, and those where the accuracy dips below the baseline, the accuracy surpasses the respective baseline at interval 4, which corresponds to 2 minutes of interaction time with PRIME.

Figure 3. Standardized convergence point metric for sequence prediction analysis.

To quantify the rate at which predictions converged towards an accurate prediction, we also calculated metrics used in the related task of goal recognition for sequence analyses [14, 22]. Specifically, we measured model performance using accuracy rate, convergence rate, convergence point, and standardized convergence point. In this context, *convergence rate* calculates the proportion of sequences where predicted outcome for the final interval is correct. In other words, this metric quantifies how well by the final interval the predictive models can accurately predict whether the student will complete the programming activity. Thus, a higher value for this metric is desirable.

Convergence point refers to the proportion of the sequence of intervals occurring before the predictive model has consistently begun to predict the correct outcome. In other words, this proportion measures a predictive model's ability to converge to an early prediction. This implies that a lower number is more desirable for this metric. The overall convergence point is the average proportion of all sequences of intervals. An issue with using convergence point to measure

how early in a sequence predictions converge is that convergence point is only calculated for sequences where the model successfully predicts the last action in a sequence (i.e., a sequence converged to the correct prediction). *Standardized convergence point* (Figure 3) takes this into account by adding a penalty factor for sequences where the last prediction is incorrect. If the prediction of the outcome (O) for a sequence of intervals (I) does not converge, then its value is calculated as $(n + p)/n$, where p is a penalty factor. For this work we set the penalty factor to 1 because of the relatively short length of the sequences investigated. As with convergence point, a lower value for these metrics is desirable.

In Table 5, we report these metrics for our early prediction models using the same train/test split as mentioned previously. Thus, the sequences of intervals for each student-activity attempt in the test set used as the sequences for these metrics. We average the rates for 10 randomly produced train/test splits to validate the results.

Table 5. Averaged rate results for logistic regression (LR) model.

Metric	
Accuracy Rate	63.96%
Convergence Rate	70.62%
Convergence Point	35.84%
Standardized Convergence Point	57.75%
F1 Score	68.87%

5. DISCUSSION

Four families of features contribute to predictive student modeling. *Prior performance*, *hint usage*, *activity progress*, and *interface interactions* all play an important role in accurately predicting student success in programming activities. The predictive models outperform baselines which use majority class prediction of each individual interval. Using these enhanced models, we found that several features stood out as more predictive.

The *prior performance* feature was the strongest positive (coefficient direction) predictor. If students have successfully completed more of their previous exercises, then they are likely to continue doing so. Because this feature accounts for successes on other activities, when students have just begun attempting activities, there will be no data to inform this feature. This is demonstrated in Table 3 when the F1 score is close to 0 for the individual family of features (Ind.) column. However, when no information is known about a student's prior success (i.e., when they are just starting their interaction), the system can use the other features to account for this. A strong negative predictor of student activity completion was the *time interval*. If a student attempts an activity and begins taking more time, the likelihood of their completing that activity may decrease. This could be due to the student not grasping the underlying concept in which the activity is centered.

Two strong positive predictors were *checkpoints passed* and *test cases passed* (activity progress), denoting how many steps a student has completed in the problem. This is a different measure than time interval, as time interval does not capture

the objective progress the student has made. Therefore, if a model is able to detect how much of the code the student has completed relative to the total code needed for the activity, this could boost predictions. The more incremental checkpoints the system designer uses to assess student code, the more likely this feature will be a strong predictor.

Within the interface interaction family of features, *block creations* served as a negative predictor, while *block deletions* served as a positive predictor. These features are fundamental to understanding a student's code. For systems that do not use built-in test cases, these can serve as core predictive features to use for this prediction task. In PRIME, students can freely create, delete, change, and move blocks according to their believed solution to the activity. Actions such as move and create may reveal a more "trial and error" approach, in which the student is attempting new ideas without knowledge of how these blocks interact. Similarly, actions such as deleting a block and changing a block could indicate when a student has tried a block configuration and no longer believes this to be the correct block configuration. In this case, the student is revising his or her answer, and this could point to a block configuration that is closer to an actual solution.

A surprising result is the fact that *hint button presses* was not one of the strongest predictors. The hint request functionality in this environment guides student problem solving at a conceptual level. Hints are designed to nudge students to consider approaches that may spark a correct move or block creation. Thus, if students request many hints, it may be that they are not getting closer to the correct answer. If they keep requesting hints without successfully completing an activity, this could indicate either a lack of effort or lack of understanding, or perhaps both. For effort, analyses would need to be performed to determine if there is a pattern with other interface interaction features that indicate little attempt on the activity. For understanding, analyses would need to be performed to determine if the student is making little progress, such as is the case in wheel-spinning [34]. One reason that hints did not serve as a stronger predictor could be the fact that there were not a consistent number of hints per activity. In addition, these hints are not hierarchical. In other words, the hints do not utilize a "bottom-out" mechanism that becomes finer-grained as the student requests more hints at the same point in their code. This type of hinting system would allow for students who are clearly experiencing an impasse (or lacking effort) to receive more explicit hints, which would likely change the predictive value of the feature.

5.1 Limitations

In this analysis, predictive models were created to determine if a student will complete a block-based programming activity. We explored the possibility of making this prediction as early as possible. While we quantified this through the improvement of accuracy over time and through the use of convergence rate and convergence point, there are no clear standards or baselines for comparing these results. Without a baseline, it is impossible to fully know how this predictive model performs in relation to other models. When determining the type of model to use, we chose logistic regression due to its relative interpretability. However, other models may have higher performance, especially when tuned appropriately. It will be important to investigate other models in future work.

Another limitation is that this analysis did not fully represent the temporal nature of the data. We created a *time interval* feature to account for 30-second intervals, but we do not treat the actions themselves as sequential features. An alternative to treating the features as sequential could be to create finer-grained intervals (varying time lengths) and to use sequential-based machine learning models, such as probabilistic graphical models or recurrent neural networks. Additionally, though the feature families were chosen to generalize well across learning environments, the underlying features are specific to this environment and may not generalize well. Further investigation is needed to understand the effectiveness of this modelling approach for both other programming environments as well as similarly structured environments from other domains.

A final limitation of this work that should be investigated in future work is level of granularity at which analyses of student code is conducted. One way to analyze student code is to perform static tests, such as in *checkpoints passed* and *test cases passed*. Another method would be to create a new representation of the code and analyze this representation, as the automated code analysis approach presented in [39].

6. CONCLUSION

With increasing interest in block-based programming environments for teaching introductory computer science, programming environments that can provide adaptive support hold considerable promise. In order for these environments to evolve beyond providing on-demand hints, there is a need to develop predictive models that can accurately and quickly identify whether a student will succeed or abandon a given activity.

To explore this potential, we created predictive student models for the PRIME block-based programming environment that were informed by four families of features: prior performance, hint usage, activity progress, and interface interaction. Evaluations showed that the models could predict student activity completion more accurately than baselines, and results also demonstrate that by splitting up student-activity attempt data into time intervals, they can make accurate early predictions. A survival-based analysis showed that by 2 minutes of student interaction time, these models consistently outperform baselines, and prior performance, time interval, and test cases passed were the most predictive features.

In future work, it will be important to investigate modeling frameworks that can better leverage sequential features of the data. Second, it will be important to explore more granular assessment rubrics of student programming artifacts, such as those that might be derived from an evidence-centered design approach [30] to drive the predictive models. Third, exploring models that integrate performance prediction with "sibling" models for help-seeking, off-task-behavior, and wheel-spinning is a promising direction for future work. Here, an ensemble of predictive models could be assembled to most effectively support novice student programming. Finally, it will be important to investigate models that operate in tandem with block-based programming and text-based programming and that best support the transition from block-based to text-based programming as students progress to increasingly complex computational problem-solving tasks.

ABSTRACT

Replication of machine learning experiments can be a useful tool to evaluate how both *modeling* and *experimental design* contribute to experimental results; however, existing replication efforts focus almost entirely on modeling alone. In this work, we conduct a three-part replication case study of a state-of-the-art LSTM dropout prediction model. In our first experiment, we replicate the original authors' methodology as precisely as possible in collaboration with the original authors. In a second experiment, we demonstrate that this initial experiment likely overestimates the generalization performance of the proposed model due to the design of its validation. In a third experiment, we attempt to achieve the previously-reported performance in a more difficult, but more relevant, hold-out set design by exploring a large space of model regularization configurations. We demonstrate that we can reduce overfitting and improve generalization performance of the model, but cannot achieve the previously-reported level of performance. This work demonstrates the importance of replication of predictive modeling experiments in education, and demonstrates how experimental design and modeling decisions can impact the extent to which model performance generalizes beyond the initial training data.

1. INTRODUCTION

The repeated verification of scientific findings is central to the construction of robust scientific knowledge, particularly in a fast-growing field such as educational data mining. This can take the form of (a) reproduction (reproducibility), using the original methods applied to the original data to reproduce the original results, and (b) replication (replicability), applying the original methods to *new* data to assess

the robustness and generalizability of the original findings. Since reproducibility is a necessary condition for replicability (an experimental procedure cannot be applied to new data if the procedure cannot be reproduced), achieving replicability requires solving the problem of reproducibility.

In this work, we discuss the reproducibility crisis in machine learning, noting specific challenges faced by applied researchers in the learning sciences, particularly in the subfields of educational data mining and learning analytics. We argue that existing frameworks for reproducible machine learning such as open code-sharing platforms and public code notebooks are valuable steps, but are insufficient to fully address the challenges both within our subfield of interest and the broader machine learning community. In particular, we argue that code-sharing does not address the breadth of challenges – experimental, methodological, and data – we face as practitioners, as Section 3 details. Instead, we propose a paradigm of *end-to-end* reproducibility for machine learning: fully reproducing (or replicating) the pipeline from raw data to model evaluation. End-to-end reproducibility is possible with current freely-available computing technologies, namely containerization.

Using an open-source platform for conducting reproducible end-to-end machine learning experiments on large-scale educational data, the MOOC Replication Framework (MORF), we conduct a three-stage replication experiment in Section 4, which is the primary contribution of this work.¹ Our case study evaluates both the experimental design, by comparing different train-test regimes, as well as the modeling, by replicating the original results and attempting to extend them via modern neural network regularization methods. We present practical recommendations based on our results in Section 5. We describe additional benefits, beyond reproducibility, afforded by MORF, and replication in machine learning more broadly, in Section 6, concluding in Section 7.

2. PRIOR WORK

2.1 The Reproducibility Crisis in Machine Learning

Much has been written about the reproducibility crisis in science, particularly in fields which conduct human subjects research such as social psychology. Recent empirical evidence has shown that issues with reproducibility are also widespread in the field of machine learning. A survey of 400 research papers from leading artificial intelligence venues shows that none of the works surveyed document all aspects necessary to fully reproduce the work; only 20-30% of the factors evaluated were adequately reported in the works surveyed [19]. A replication study of deep reinforcement learning algorithms [21] show that the variance inherent to statistical algorithms, the use of different hyperparameter settings, and even different random number generation seeds contribute to a lack of reproducibility in machine learning research and have a direct impact on whether experimental results and baseline model implementations replicate. A survey of 30 machine learning studies in text mining identified poor reproducibility due to lack of access to data, software environment, randomization control, and implementation methods [28]. None of the 30 works surveyed provided source code, and only one of 16 applicable studies provided an executable to be used to reproduce the experiments.

These reproducibility issues are partly attributable to culture and convention. A survey of authors published in the *Journal of Machine Learning Research* found that roughly one third intentionally did not make their implementations available, for reasons including a lack of professional incentives, a reluctance to publish messy code, and the convention that doing so is optional [33]. [30] observes that only five of 125 published articles in the journal *Biostatistics* have passed the (voluntary) reproducibility review since its inception two years prior, yet considers this effort “successful” compared to the reproducibility of previous work.

As big data and machine learning permeate disciplines, this crisis in replication has also affected other fields of study, including the learning sciences. This is especially relevant in cases of very large datasets where the majority of learning is computer-mediated, such as in Massive Open Online Courses (MOOCs). For example, [16] showed that a large-scale replication of machine learning models led to substantially different conclusions about the optimal modeling techniques for MOOC dropout, with several findings replicating significantly in the *opposite* direction of the original study (which was conducted on only a single MOOC). In an attempted replication of the “deep knowledge tracing” method originally introduced in [31], the results showed that much simpler methods could achieve equivalent performance, and that the performance gains demonstrated in the original work were at least partially due to data leakage [24]. Somewhat more favorably, in [2], the authors find that 12 of 15 experimental findings in MOOCs replicated using a production-rule framework, but an additional two findings replicated significantly in the *opposite* direction.

2.2 Existing Tools for Reproducible Machine Learning

An exhaustive survey of tools and platforms to support reproducible machine learning research is beyond the scope of this paper. However, we include a brief survey of tools most relevant to reproducible machine learning for predictive analytics in education.

OpenML [35] is “an open, organized, online ecosystem for machine learning” that allows users to create data science pipelines to address specific “tasks”, such as classification and clustering. The OpenAI Gym is an open-source interface for developing and comparing reinforcement learning algorithms [6]. Its wide use for both teaching and research serve as an example of how a subfield can create and adopt shared tools that meet researchers’ needs while enhancing reproducibility. Recently, several publishing platforms dedicated to reproducible computational research have also formed, such as ReScience ², CodaLab ³, and WholeTail [5]. These platforms unify code, data, computation, and presentation in a single location. CodaLab and WholeTail also use Docker containerization to ensure reproducibility.

Each of these platforms is an important step toward reproducible machine learning research, and many of them address key barriers. However, these tools are insufficient for many types of machine learning tasks, including supervised learning with large-scale behavioral data from MOOCs. In particular, none of these platforms supports replication where the underlying data sets are privacy-restricted and cannot be publicly shared. In some cases, such as WholeTail, the platform scope is explicitly limited to public (non-restricted) datasets [5]. However, in educational data, many of the types of unanonymizable data that are privacy-restricted are also necessary for analysis (such as the text of discussion forum postings, IP addresses, or student names). Such restrictions are also likely to drive away machine learning researchers from working with this data, as gaining access to unprocessed raw educational data can be difficult or impossible without close collaborators and strong institutional support. Even with institutional support, government regulations such as the Family Educational Rights and Privacy Act (FERPA) may restrict or complicate data sharing.

3. THE MOOC REPLICATION FRAMEWORK

The replication crisis is the result of a confluence of forces which must be collectively addressed in order to achieve end-to-end reproducibility. Prior work has identified three groups of challenges: experimental, methodological, and data challenges [17]. No existing solution discussed in Section 2.2 currently addresses all three barriers. In this section, we outline three key barriers to reproducibility, and describe how these barriers are addressed by the MOOC Replication Framework (MORF), the research tool used to conduct this experiment.

MORF itself is a Python toolkit, accompanied by a platform-

²<http://rescience.github.io/about/>

³<http://codalab.org/>

End-To-End Machine Learning

Figure 1: End-to-end reproducibility requires addressing data, technical, and methodological issues with reproducibility. Replication of the computational environment, in particular, is key to replicating this complete pipeline from raw data to results. Each of the four stages of the supervised learning pipeline executed inside the computational environment are encapsulated in MORF’s execution model (see Section 3).

as-a-service (the “MORF Platform”), which collectively address the challenges faced by researchers studying large-scale online learning data noted above [17].⁴

Users submit jobs to the MORF Platform using short, 4-5 line “controller” scripts which guide the execution of each stage of the end-to-end supervised learning pipeline (extract, train, test, and evaluate) shown in Figure 1. The use of controller scripts is a common approach to conducting reproducible computational research [25]. MORF’s combination of containerization and controller scripts allow the user to manage low-level experimental details (operating system and software dependencies, feature engineering methods, and statistical modeling) by constructing a Docker container which is submitted to MORF for execution. MORF manages high-level implementation details (parallelization, data wrangling, caching of results) by “bringing the computation to the data.” This prevents the download of sensitive raw data (currently, this includes the complete raw data exports from over 270 MOOCs offered by two institutions [17]). The containers used to execute each job are persisted in MORF’s public Docker Cloud repository, and the configuration file and controller scripts are persisted in Zenodo and assigned a unique Digital Object Identifier (DOI). This yields a reproducible end-to-end pipeline that is flexible, easy to use, and computationally efficient.

MORF eases the computational expense of conducting such research at scale by providing nearly an order of magnitude greater computational infrastructure than any of the platforms discussed in Section 2.2, and out-of-the-box parallelization to utilize it. See [17] for a more thorough comparison to other platforms.

3.1 Experimental Reproducibility via Containerization

Experimental challenges with reproducibility relate to reproducing the exact experimental protocol [17]. It has been noted that code-sharing alone is insufficient to guarantee reproducibility in computational research. For example, [10] showed that the published code accompanying 20% of their large sample of 613 published computer systems papers failed to build or run, and in total, it was not possible to verify or reproduce 75.1% of studies surveyed using the

artifacts provided in publication.

Even when code is available, other technical issues can prevent reproducibility in research workflows [25]. These include *code rot*, in which code becomes non-functional or its functionality changes as the underlying dependencies change over time (for example, an update to a data processing library which breaks backwards compatibility, or a modified implementation of an algorithm which changes experimental results), as well as *dependency hell*, in which configuring the software dependencies necessary to install or run code prevents successful execution [3]. This complex web of interdependencies is rarely described or documented in published machine learning and computational science work [19, 28], despite over two decades of evidence that it is a necessary condition for reproducing computational results [7].

MORF uses containerization to support end-to-end reproducibility (Figure 1). The Docker containers submitted to MORF fully encapsulate the code, software dependencies, and execution environment of an end-to-end machine learning experiment in a single file, ensuring end-to-end reproducibility and enabling sharing of the containerized experiment. Docker containers were developed to resolve many of the experimental reproducibility challenges described above in software development contexts [27], and are frequently used in industrial software applications, computational modeling, and computer systems research [3, 9, 23]. A major advantage of containerization over simple code-sharing is that containers fully reproduce the entire execution environment of the experiment, including code, software dependencies, and operating system libraries. Docker containers are more lightweight than a full virtual machine, but achieve the same level of reproducibility [27, 23]. Building Docker containers requires only a single Dockerfile (akin to a makefile) which contains instructions for building the environment. This imposes minimal additional burden on researchers relative to configuring, programming, and executing an experiment, but achieves a considerable increase in reproducibility. While other existing machine learning research platforms sometimes utilize Docker “under the hood,” this limits users’ ability to fully leverage containerization by configuring or sharing these environments. We are not aware of any platform which allows users to build and submit Docker images directly for execution as MORF does.

As part of MORF, we are assembling an open-source library of pre-built Docker containers to replicate experiments con-

⁴The MORF website, which includes documentation and short tutorials, is at <https://educational-technology-collective.github.io/morf/>

ducted on MORF to serve as shared baseline implementations. These containers can be loaded with a single line of code, allowing the research community to replicate, fork, interrogate, modify, and extend the results presented here⁵.

3.2 Methodological Reproducibility via Platform Architecture

Existing work on reproducibility largely focuses on strictly technical challenges, but as our experiment in Section 4 shows, methodological issues are at least as important. *Methodological challenges* to reproducibility reflect the methods of the study, such as its procedure for model tuning or statistical evaluation. Poor methodological decisions can lead to a lack of inferential reproducibility [19]. We see such issues in e.g. the use of biased model evaluation procedures [8, 36]; improperly-calibrated statistical tests for classifier comparison [12]; large-scale hypothesis testing where thousands of hypotheses or models are tested at once, such as in massive unreported searches of the hyperparameter space without statistical evaluation or appropriate corrections, or “random seed hacking,” wherein the random number generator itself is systematically searched in order to make a target model’s performance appear best or a baseline model worse [21].

MORF is designed to provide sensible default methodological procedures for many machine learning tasks, such as model evaluation, in practical terms nudging researchers to make sound choices. For example, MORF avoids the use of cross-validation for model evaluation: The prediction tasks to which most MOOC models aspire are prediction of *future* student performance (i.e., in an ongoing course where the true labels – such as whether a student will drop out – are unknown at the time of prediction). As such, using cross-validation within a MOOC session, when the outcome of interest is accuracy on a *future* MOOC session, provides an unrealistic and potentially misleading estimate of model performance. Prior work has demonstrated that within-session cross-validation in the MOOC domain can produce overly favorable estimates of classification performance on a future (unseen) course or future session from the same course [37, 4]. Adopting more effective model evaluation techniques by default requires no additional work for MORF users, and ensures that work produced on the MORF platform follows effective model evaluation procedures. MORF’s large data repository also prevents users from having to utilize only a single dataset for both training and testing; with many iterations of many unique MOOCs available, users can have considerable training data available while also conducting effectively-designed experiments with ample and representative test data.

3.3 Data Reproducibility via Execute-Against Access

Data reproducibility concerns the availability of data itself. In many domains, making raw data available is more an issue of convention than a true barrier to reproducibility. However, in the case of educational data mining, data are often governed by strict privacy regulations which protect the privacy of student education records. Similar restrictions af-

⁵The experiment presented below can be loaded by running `docker pull themorf/morf-public:fy2015-replication` in the terminal of any computer with Docker installed.

fect many other fields, from the health sciences to computational nuclear physics [25]. As a result, researchers are often legally prohibited from making their data available. Efforts such as [26] and [20] have attempted to address this problem in education by only releasing non-identifiable data, but many analyses require the original, unprocessed data for a full replication. Indeed, restricted data sharing is one of the main factors (in our experience) hindering generalizability analysis in educational data mining: investigators are generally limited to one or two courses worth of data (e.g. the courses they instruct or specific publicly available courses), and models are often overfit to these datasets.

MORF achieves data reproducibility while also meeting data privacy restrictions by providing strictly “execute-against” access to underlying data [17]. Most MOOCs are generated by a small number of platforms (e.g. Coursera, edX), and all courses from a given platform use publicly-documented data schemas, e.g. [11]. Thus, users can develop experiments using their own data from a given platform – or even the public documentation – and then submit these experiments for MORF to execute against *any* other course from that platform. This enables MORF to currently provide an interface to over 270 unique sessions of more than 70 unique courses offered by two different institutions on the Coursera platform, and to execute containerized experiments against this data in a secure, sandboxed environment by utilizing the shared public schema of the datasets [11]. These shared public data schemas also ensure that existing experiments in MORF can be replicated against new data (from the same MOOC platform) as it becomes available.

4. REPLICATION EXPERIMENT: NEURAL MOOC DROPOUT MODELS

In the remainder of this paper, we conduct an in-depth exploration of previously-published MOOC dropout prediction models using MORF. Neural models have demonstrated the capacity to achieve state-of-the-art performance on a wide variety of modeling and prediction tasks, from language modeling to computer vision. Their application to MOOC research has also demonstrated initial promising results [13, 29] due to their ability to model complex functional relationships between student behavior data and learning outcomes, but such research has been limited. In this section, we use MORF to replicate a comparison conducted in [13], which compares several machine learning algorithms using a set of seven activity features (e.g. number of lecture videos viewed, quizzes attempted, and discussion forum posts for each student) over each week in a MOOC in order to predict a binary dropout label indicating whether a user showed activity in the final week of a course.

This study is an ideal candidate for replication because it has been highly cited in the field, but compares six models over five weeks of a MOOC (effectively testing $\frac{6 \cdot 5 \cdot 5}{2} = 75$ pairwise hypotheses) using cross-validation on only a single dataset. This testing of many hypotheses/comparisons, with only a single observation for each, can lead to poor methodological reproducibility and provides no information about the variability of the estimates, relative to their magnitude [14]. Particularly because this experiment was concerned with empirical performance (in order to inform future “early warning” dropout prediction systems), obtaining an accurate

estimate of models' expected performance on *future* course sessions across a large, representative dataset can provide insight into the generalizability of these findings. The use of within-session cross-validation to draw conclusions about future generalization performance remains common in MOOC prediction research [15].

We present the results of our replication in Section 4.1, which matches the authors' original comparisons and their experimental design. The original work evaluated three different definitions of MOOC dropout; for tractability within this paper, we strictly replicate "Definition 1" of dropout from [13], which is the most commonly-used definition of dropout in MOOC research [16]. In Section 4.2, we present the results of a second experiment, which compares the same models using a different experimental setup (predicting on future course sessions) in order to demonstrate that the original experimental design overestimates the generalization performance of these models, likely due to overfitting. Our experimental analysis quantifies this overestimation and provides evidence using statistical tests. Finally, in Section 4.3, we use a comprehensive hyperparameter tuning and model evaluation procedure to show that we can improve the generalization performance of the LSTM model using batch normalization, but that the addition of two other neural network regularization methods does not further improve either the LSTM or RNN model. We also present detailed information on a variety of parameterizations examined in order to inform future work.

4.1 Experiment 1: Full Replication With Original Design

In our first experiment, we replicated the original experiment using the original design – estimating model performance via cross-validation within a single course – across 45 unique MOOCs using MORF, in consultation with the original authors. Results are shown in Figure 2.

The original work concluded that a Long Short-Term Memory (LSTM) neural network model “beats the ... other proposed methods by a large margin” [13], pp.1. – a result which matches the advances that neural models have made in other domains. Our results in Experiment 1 show, however, that (1) LSTM is actually one of the lowest-performing models, with the lowest average performance of any model tested in weeks 4 and 5; (2) in most cases, the 95% confidence intervals for algorithm performance overlap, and so we cannot conclude that there is a difference in performance between any but the very best and worst models evaluated, even without applying corrections to adjust for the use of multiple comparisons; and (3) observed performance of all models is lower than in [13], particularly in later weeks of the course.

We hypothesize that the relatively poor performance of LSTM may be due to overfitting on the dataset used in the original experiment in [13]. Particularly when using cross-validation for model selection on a single dataset with a highly flexible model such as LSTM, the experimental design of the original work was quite susceptible to overfitting. Overfitting seems particularly likely because no procedure for selecting hyperparameters was reported in [13], and some key hyperparameter settings for the LSTM model

(e.g. batch size) were not reported at all. These hyperparameters were not available even after correspondence with the authors, who did not record them and no longer had the original code available (which itself points to the need for reliable long-term reproducibility solutions such as MORF). The need for detailed hyperparameter reporting in reproducible research has been noted previously [21].

(2) shows the advantage of using MORF's large data repository, which allows us to observe variability in each algorithm's performance across many MOOCs to form confidence intervals for algorithm performance. Experiment 1 suggests that while differences in average performance may exist, these are too small to be interpreted as genuine and not spurious – particularly in light of the results shown in Figure 3, which shows that the differences due to cross-validation bias are larger than the observed differences between algorithms in most comparisons. We note that the out-of-fold prediction error in each cross-validation iteration could have been used to provide an estimate of the variability in model performance when applied to new data in [13]; however, this was not provided in the original work. In any case, having more datasets available makes the estimation of this variability more reliable than would have been possible with only one course.

Finally, the generally lower observed performance for all models may also be due to overfitting, and particularly due to the experimental design. Experiment 1 uses an identical design to [13]. However, [13] uses only a single course (in comparison to the 45 courses used in Experiment 1), which would have permitted tuning many of the hyperparameters germane to neural models (e.g. learning rate, activation functions, number of training epochs, batch size, number of hidden layers and units) specifically to optimize performance on this individual course. In contrast, when using the large, diverse set of courses in MORF, over-tuning such hyperparameters to an individual course would be disadvantageous (and extremely difficult, due to the diversity of course sizes and learner populations represented in MORF [17]). When fitting multiple courses at once (as in MORF), the incentive is instead to find a set of hyperparameters which generalizes to many different types of courses.

The results of this experiment demonstrate the importance of using large, diverse datasets for machine learning experiments, and of performing multiple experimental replications. Additionally, these results demonstrate that simpler models – such as RNN, radial SVM, and logistic regression – may achieve equivalent or better performance than LSTM for MOOC dropout prediction. Our results, which are contrary to the findings of the original study, also suggest that further replication is necessary to identify the most effective algorithms for MOOC dropout prediction, as we perform no hyperparameter tuning in Experiment 1 and only replicate the original models and features.

4.2 Experiment 2: Replication With Improved Experimental Design

The original aim of the dropout prediction model in [13] was to achieve accurate prediction on *future* courses. Prior work has shown considerable differences in prediction results depending on the prediction and transfer architectures

Figure 2: Original results from [13] (left) and replication results using the MOOC Replication Framework evaluated using a held-out future course session (center) and cross-validation (right). 95% confidence intervals shown. IOHMM not replicated due to lack of an open-source implementation which supported prediction.

used, particularly when predicting on the same course session used for model training instead of a future iteration of the same course [37, 4]. In the case of the original experiment, the cross-validation design was due to necessity: data from only a single MOOC was available to the original authors, and the prediction on out-of-fold data within the same session was used. However, MORF makes *all* sessions of each course available, with 45 courses having at least two sessions. Therefore, in this section, we conduct an experiment which uses the same modeling methods as the original experiment, but do so using a true holdout architecture, where each model is trained on the first $n - 1$ sessions of a MOOC, and is tested on the final session. We refer to this experiment as Experiment 2. Note that only the *design* of the prediction experiment is changed from Experiment 1.

The results of Experiment 2 are shown in the right panel of Figure 2. The contrast between the center (cross-validation) and right (holdout) panels demonstrates the optimistic bias which can be introduced by evaluating generalization performance via within-session cross-validation without the use of an independent hold-out session [36]. This matches previous results demonstrating that the bias of performance estimates when models are optimized over cross-validation folds can often exceed the difference between learning algorithms [8]. These results are further demonstrated by Figure 3, which shows a persistent positive bias for model evaluation performed by cross-validation versus the “true” performance on a future course session. A two-sided Wilcoxon signed-rank test of a null hypothesis of equivalence between the holdout and cross-validated experimental results, where each model-week combination was treated as an observation, was rejected with $p < 2.2 \times 10^{-16}$.

A notable result from Figure 3 is that the observed 2σ upper-bound on the bias due to cross-validation is around begins at roughly 0.035 AUC units when predicting after a single week, and increases to over 0.08 AUC points in later weeks. This difference due to design is as large as the difference between the highest-performing model and the two next-highest performing models in every week of the original experiment (see left panel of Figure 2). This shows that biases introduced by experimental design can entirely overshadow experimental effects, and should be a particularly strong call to action for the EDM community.

The findings of Experiment 2 are threefold. First, it demon-

strates that using within-course cross-validation to estimate generalization performance on future course sessions introduces a significant positive bias. This should serve both as a call for machine learning researchers to dedicate additional attention to the experimental design of machine learning experiments, as well as a call to practitioners to rigorously evaluate models prior to their deployment for prediction. Second, we quantify this bias, showing that in practice the bias roughly falls in the 95% CI $[0, 0.05]$ – where the upper-bound is larger than the difference between learning algorithms in the original work. Third, these results provide further evidence that the original results presented in [13] may have been overfit to the data in that work, and that the generalization performance of such a model may be lower than what was suggested by the initial results from [13].

4.3 Experiment 3: Improving Model Generalization Performance via Regularization

In the previous two experiments, we presented results which called into question some findings of the initial study in [13], that neural models can significantly improve MOOC dropout prediction. Our observations largely centered on the problematic potential for overfitting and optimistic bias due to experimental design in [13]. In this section, we show that the consequences of overfitting can be at least partially ameliorated by using modern regularization methods for neural models. This section is intended to explore (a) whether we can provide further evidence that the original models were overfit to the data in [13], and (b) whether we can improve the models’ generalization performance, and still achieve state-of-the-art dropout prediction performance with these models, through the use of regularization to reduce overfitting. In particular, we explore the recurrent neural network (“vanilla RNN”) and Long Short-Term Memory (LSTM) models from the original study, but introduce different architectures and explore various configurations of three regularization methods, none of which were in the original work. We show that we can approach, but not match, the performance reported in [13], even when predicting on future course sessions, by applying and tuning these regularizations to the RNN and LSTM models.

Regularization is a modification made to a learning algorithm that is intended to reduce its generalization error but not its training error [18]. We explore three types of regularization in this experiment, which we describe below.

Comparison of Cross-Validation vs. Holdout Experiment Results

Figure 3: Comparison of AUC estimates from identical experiments using a holdout vs. within-course cross-validation evaluation architecture. These results show a persistent positive bias when within-course cross-validation is used to estimate predictive performance on a future, held-out session of a MOOC.

Dropout [34] randomly drops neural network units (along with their connections) during each training iteration with probability p . We test models with $p = \{0, 0.2\}$

Batch normalization [22] normalizes each feature in every minibatch of data during training, which stabilizes model training by reducing covariate shift (large changes in parameter updates due to differences in the distribution across features) and preventing small changes to the parameters from amplifying into larger and suboptimal changes in activations in gradients. We test models with and without batch normalization for each model.

L2 Regularization perhaps the most common regularization method in modern deep learning research [18], L2 regularization adds a penalty term to the loss function based on the L2 norm of the network weights with the parameter λ controlling the level of penalization (higher λ yields greater regularization). We test $\lambda = \{0, 0.01, 0.001\}$ for each model.

The study under replication was published in 2015, and since then, research on the regularization of neural models has advanced considerably. Dropout was only originally proposed in 2014, and batch normalization in 2015, so these techniques were still quite new at the time of publication of [13] and implementations were not widely available as part of standard neural network software, as they are now. As a result, the original publication quite reasonably did not explore these novel methods, despite their potential to improve their results in practice.

Experiment 3 evaluates dropout prediction after four weeks of the course (this is the final time point shown in Figure 2). Evaluating the full range of all weekly prediction tasks was beyond the scope of this experiment, as even the experiment here required testing 72 different hyperparameter configurations (36 LSTM and 36 RNN models) across 45 courses, resulting in a total of 3,240 total models trained. We choose the week 4 prediction task because, after four weeks, there would be maximal data for models to learn from – and also, potentially, for models to overfit to. Week 4 prediction therefore provides the best opportunity to separate models with strong generalization performance from

models which overfit.

Results from Experiment 3 are shown in Figure 4. We statistically evaluate the model comparisons, and visualize the results, using the Bayesian method of [14]. This method uses a hierarchical Bayesian model to evaluate all pairwise comparisons of a set of k models across N datasets by accounting for the correlation in performance across models and datasets. While the original comparison also accounts for fold-level correlation when applying the testing procedure to the results of a cross-validation procedure, here we only have a single estimate for each dataset, and this simply adds slightly more uncertainty to our estimation, which will tend to make the model more conservative (less likely to make a decision). The procedure estimates three probabilities for each pair of classifiers X and Y : $\mathbb{P}(X > Y)$, $\mathbb{P}(ROPE)$, $\mathbb{P}(X < Y)$, where ROPE indicates that the difference in performance between the models is within a “region of practical equivalence”, which in this experiment is set to $ROPE = 0.01$. We use a decision threshold of 0.9, which means that the procedure makes a “decision” (indicated by a colored entry in the windowpane plot of Figure 4) only when the posterior probability of one of the events is greater than or equal to 0.9; otherwise, the procedure makes no decision (indicated by a blank white entry in Figure 4).

The results in Figure 4 demonstrate that batch normalization considerably improves the LSTM model – all LSTM models with batch normalization performed better, on average, than any LSTM model without batch normalization. The hierarchical Bayesian model used to compare the modeling results across the 45 course in MORF indicated that almost all of the batch-normalized LSTM models were within the “region of practical equivalence”, or ROPE, indicating a high posterior probability that these models achieve practically equivalent predictive performance (in this experiment, a ROPE of 0.01 was used, meaning that a decision of ROPE indicates a confident decision that models’ test AUC differed by less than 0.01). Tuning of the other hyperparameters (L2 regularization λ , and dropout probability p) had little effect on observed model performance, with almost all hyperparameter configurations being practically equivalent within a fixed batch normalization group. These results suggest that

Figure 4: Windowpane plots for LSTM model tuning experiment (left) and RNN model tuning experiment (right). Batch normalization considerably improves the LSTM model. Other regularization methods (L2 regularization, dropout) show little effect. The RNN shows stable performance with a variety of configurations.

the LSTM model, which had considerably more parameters, was likely overfitting to the data – and that the different distributions across the different input features (which is countered by batch normalization) were a strong factor contributing to this overfitting. The LSTM model with the highest average performance, with $p = 0.0, h = 10, \lambda = 0.0$ and batch normalization, achieved a mean AUC of 0.726 on the MORF dataset – only 0.002 less than the best RNN model in Experiment 3.

Figure 4 shows a more complicated picture with respect to the RNN model. Generally, the results show that the RNN performance is more robust to the hyperparameters: the RNN achieves practically equivalent performance with a range of settings. For example, models with both 10 and 20 hidden units, and with every λ value considered, achieve performance practically equivalent to the highest-performing model. The exception to this robustness is dropout – every RNN in the “family” of best models (those with performance equivalent to the highest-performing model, as in [14]) had no dropout, or $p = 0.0$. The RNN model with the highest average performance, with $p = 0.0, h = 20, \lambda = 0.01$, achieved a mean AUC of 0.728.

Collectively, these results support the hypothesis that the LSTM model as parameterized in the original experiment tends to overfit on standard-sized MOOC datasets, while providing evidence that the RNN model is less prone to overfitting. The results also show that the LSTM model can be improved, with performance to match the best RNN model, through the use of regularization. For reference, the LSTM model in the original experiment (with a single layer and 20 hidden units) has 2,261 trainable parameters, while the RNN model has 581 tunable parameters. Regularization is less likely to impact a properly-parameterized model when sufficient data is provided, while its impact can be much more evident when a model has too many free parameters for the available data, as we see in the contrast between the LSTM and RNN results of Figure 4 and the lack of effect on RNN performance (mean AUC for the original RNN show in in Experiment 2 was 0.727 at week 5).

5. IMPLICATIONS FOR PRACTICE

5.1 Experimental Design for Predictive Modeling in EDM

The current work demonstrates that experimental design can have important implications for the conclusions generated from a machine learning experiment. Our results show that both researchers and practitioners should clearly identify the hypotheses to be tested by a machine learning experiment, or the goals of a deployed model, and then utilize experimental designs which allow for inference about the types of prediction scenarios to be encountered in the task of interest. Cross-validation can be useful in evaluating a specific dataset, e.g. by fitting an explanatory model where the interpretation of learned parameters is used to understand the dataset. Cross-validation may also be useful when the available data is limited. However, in cases where prediction on a future course or generalization to *new* data are of interest, using data from a future course or session will provide more reliable estimates of model performance. For further discussion of the design of machine learning experiments, see [1].

5.2 Hyperparameter Tuning for Neural Models in EDM

The current work provides evidence regarding the importance of effective model tuning and regularization in educational data mining. In practice, educational models need to operate effectively in a wide variety of scenarios. Predictive models in EDM are often required to obtain reasonable performance even as the dataset size, target population, and even data attributes change across course populations, institutions, or platforms, making model robustness a key consideration.

This experiment adds to an existing body of evidence (e.g. [14]) that selecting an appropriate statistical model can affect predictive performance much more than hyperparameter selection (when reasonable hyperparameters are selected). The introduction of regularization methods can improve models which are overfit, but has little impact on those which are not overfit. However, introducing regularization as an additional experimental factor may be particularly challenging

as it introduces an additional dimension of model tuning and can considerably increase the computational cost of experiments.

Our finding that batch normalization, in particular, improved the generalization performance of the LSTM model suggests that normalization of counting-based features – which can be highly skewed and show very different distributions for different types of actions – is an important tool for use in educational models.

6. BEYOND VERIFICATION: ADDITIONAL ADVANTAGES OF REPLICATION IN MACHINE LEARNING

Much prior work on reproducibility has focused on verification – ensuring that published results are true and can be reproduced. However, end-to-end reproducible machine learning frameworks, such as MORF, provide benefits beyond mere verification, including:

“Gold standard” benchmarking: open replication platforms allow for the comparison of results which were previously not comparable, having been conducted on different data. The use of such benchmarking datasets has contributed to the rapid advance of fields such as computer vision (e.g. MNIST, IMAGENET), natural language processing (Penn Tree Bank, Brown corpus), and computational neuroscience (openfMRI). These datasets have been particularly impactful in fields where it is difficult or expensive to collect, label, or share data (as is the case with MOOC data, due to legal restrictions on sharing and access). This can help advance the “state of the art” by providing a common performance reference which is currently missing in MOOC research.

Shared baseline implementations: We noted above that variability in so-called “baseline” or reference implementations of prior work has contributed to concerns about reproducibility in the field [21]. By providing fully-executable versions of existing experiments, MORF ameliorates these issues, allowing for all future work to properly compare to the exact previous implementation of a baseline method.

Forkability: containerization produces a ready-made executable which fully encompasses the code and execution environment of an experiment. These can be readily shared and “forked” much in the same way code is “forked” from a git repository. This allows MOOC researchers to build off of others’ work by modifying part or all of an end-to-end pipeline (for example, by experimenting with different statistical algorithms but using the same feature set as a previous experiment) within the same software ecosystem.

Generalizability analysis: Each successive replication of an experiment provides information about its generalizability. Evaluating the generalizability of experiments has been a challenge in MOOC research to date, where studies conducted on restricted and often homogeneous datasets are common [15]. When containerized end-to-end implementations are available, replicating these analyses on new data – even data which are not publicly available but share the schema of the original data – becomes as straightforward as

running the containerized experiment against new data.

Sensitivity Analysis: This technique, used widely in Bayesian analysis, evaluates how changes to the underlying assumptions or hyperparameters affect model fit and performance. Such an evaluation can provide useful information about a model’s robustness and potential to generalize to new data. Without being able to fully reproduce a model on the original data, sensitivity analyses are not possible. In MORF, such analyses can be conducted by simply forking and modifying the containerized version of the original experiment, then re-executing it against the same data. These analyses can also include so-called *ablation analyses*, wherein individual components are removed from a model to observe their contribution to the results, as well as *slicing analyses*, where fine-grained analysis of performance across different subgroups (e.g. demographic groups) is explored [32].

Full Pipeline Evaluation: Each stage of an end-to-end machine learning experiment (feature extraction, algorithm selection, model training, model evaluation) can be done in many different ways. Each stage also affects the others (for example, some algorithms might perform best with large feature spaces; others might perform poorly with many correlated features). However, current research usually evaluates only one or two components of this pipeline (e.g. training several algorithms and tuning their hyperparameters on a fixed feature set). Not only are the remaining stages often described in poor detail or not at all [19]; such work also leaves future researchers unable to evaluate the synergy between different aspects of the end-to-end pipeline in a published experiment (for example, exploring whether an algorithm’s performance improves with a different feature set). MORF fully encapsulates this end-to-end pipeline for a given experiment and it makes it available for modification to any other researcher.

Meta-Analysis: While meta-analyses are common in fields with robust empirical research bases, such analyses have been less common in the field of machine learning, which has an emphasis on novelty. The open availability of executable machine learning experiments affords detailed meta-analyses by providing complete results of all modeling stages for meta-analysis.

7. CONCLUSION

Further attention and analysis should be dedicated to replication in the field of educational data mining, and specifically to MOOC dropout prediction. This work proposes a paradigm of end-to-end reproducibility using the MOOC Replication Framework. Our case study in replication using MORF demonstrates the insights that can be gained from replication studies in EDM, and the importance of factors related to experimental design.

8. ACKNOWLEDGEMENTS

An earlier version of this work was presented at the Workshop on Reproducibility in Machine Learning at the 2018 International Conference on Machine Learning. We would like to thank the workshop organizers and participants for useful feedback on this work. We would also like to acknowledge the helpful assistance of the original authors of [13] in conducting this replication.

ABSTRACT

Students' interactions with online tools can provide us with insights into their study and work habits. Prior research has shown that these habits, even as simple as the number of actions or the time spent on online platforms can distinguish between the higher performing students and low-performers. These habits are also often used to predict students' performance in classes. One key feature of these actions that is often overlooked is how and when the students transition between different online platforms. In this work, we study sequences of student transitions between online tools in blended courses and identify which habits make the most difference between the higher and lower performing groups. While our results showed that most of the time students focus on a single tool, we were able to find patterns in their transitions to differentiate high and low performing groups. These findings can help instructors to provide procedural guidance to the students, as well as to identify harmful habits and make timely interventions.

1. INTRODUCTION

Modern blended classrooms are defined by suites of educational tools such as learning management systems, online forums, intelligent textbooks, video lectures, groupware tools, and even ticketing systems for office hours. The ubiquity of such tools provides researchers with a rich amount of data on students' study behaviors, work habits, and their learning trajectories. This data can help researchers to identify good and bad study habits among students as well as to define measures for estimating students' performance early on in the courses. Large datasets of this type first became available in Massive Open Online Courses (MOOCs) that have supported informative research on students'

online study habits. While these tools have now become the norm in many classroom settings and while there has been substantial research on how students use the individual tools, we have far less understanding of how students work across tools and how different patterns of use may affect their learning. Our goal in this research is to address this question through the use of sequence mining. By developing a better understanding of student activities in different online systems and their transitions between these tools, we can provide the instructors with insight on how their students usually behave when they are not in class.

Prior research has shown that there are several features easily extracted from user logs that can distinguish high performing students from the lower performing ones. Researchers have found several informative features such as number of videos watched per week, completing assignments [27], starting early [28, 34], or skipping videos and assignments [12] that were associated with students' performance and dropout in MOOCs. Studies in blended courses showed that features such as course attendance, web page views, number of watched videos, number of pauses in videos, and the number of attempts before getting each question right are correlating with student dropouts [6].

More recent work in MOOCs, Intelligent Tutoring Systems (ITSs), and blended courses has focused on grouping the student activities into study sessions and analyzing these sessions and the sequence of students' actions in them. Some researchers have analyzed features based upon these sessions in MOOCs and blended courses, such as the duration [2, 29]. However, those studies overlook the patterns of student transitions between different states or different tools. Other researchers have studied the sequences of student actions in each session, but most of those studies are focused on MOOCs or ITSs and not many of them have focused on blended courses and the data collected from the several tools that the students use for these classes. Some of these studies have relied on Hidden Markov Models on the sequences of student actions and compared the diagrams between high and low performing students (e.g. [8, 10, 14]), while others have clustered these sequences to find groups of similarly behaving students in classes (e.g. [4, 11, 7, 17, 18, 19, 25, 30]). These studies have often been able to identify relevant clusters

A Sequence Analysis of the Student Transitions between Online Platforms" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 59 - 68

among the students such as “confirmers” and “non-confirmers” [11] or “behind”, “on-track”, “auditing”, and “out” [17]. Also, other sets of studies have performed differential pattern mining on such sequences to find the patterns that are different between high and low performing students [16, 15, 13, 24]. And finally, another part of this research treats the sequences of actions as strings and uses analysis of N-grams to identify the popular trends in student activities and transitions [22, 5, 31, 32]. These methods are helpful in revealing many of the students’ behavioral patterns and the differences between the different performance groups, but are mostly focused on MOOCs or ITSSs.

Despite the extensive research in this area on MOOCs and ITSSs, studies on student transactions in blended courses are limited and most of them focus on correct/incorrect attempts on the same platform (e.g. the assignment submission systems) [11]. In this work, we collected activity logs from four online platforms for two offerings of two on-campus classes at North Carolina State University. In these classes, Piazza was used as a discussion forum, Moodle as a Learning Management System (LMS) was the means of sharing the course material and assignments, Github was used in one class as a version control as well as a code submission tool for the projects, and WebAssign was used for assignment submissions and automated grading in the other class. We aligned the logs into a single coherent transaction record, grouped the individual student actions into study sessions, and extracted the sequences of student actions from them. Finally, we labeled the students as the “Distinction” group who gained an A- or above and the “Non-distinction” group who gained a B+ or below in these courses and used N-gram analysis as well as Apriori studies to find the answers to the following research questions:

- RQ1** What are the most common transitions between different course tools?
- RQ2** Which transitions are significantly different between the distinction and non-distinction groups?

The answers to these questions can help us understand the trends of student activities better, to find key differences between high-performing students and the lower performing ones, and help the instructors to provide guidance to the students as they work or identify harmful patterns early in the semesters.

2. LITERATURE REVIEW

2.1 Students’ Online Activity Analysis

Since detailed online student logs have been available for the MOOCs, there have been extensive studies of student behaviors using these logs to identify their association with the students’ performance and attrition. Even simple measures such as number of videos watched are shown to be predictive of students’ attrition and performance in MOOCs. Some examples of these features include the number of videos watched per week, whether the student watched all of the lectures, or completed all of the assignments [27]. They also included joining the course early [28, 34], skipping videos or assignments, assignment performance [12], spending more time on each assignment [3], the number of lecture views/downloads, quiz attempts, and forum views/-posts/comments [9]. Some researchers such as Yang et al. have gone further and constructed more complex features to represent student confusion and shown that increased confusion is associated with dropout in MOOCs [33]. Chen et al. has studied

blended courses and has also shown that features such as course attendance, web page views, videos watched, video pauses, and assignment attempts are also correlated with student dropout [6]. All of these features, while informative, overlook an important part of the information that online logs provide us: the sequences of actions and transitions among different platforms.

To analyze a group of student actions as a whole, researchers have suggested defining study sessions. Prior work has suggested different methods for defining study sessions such as having a “fixed duration” [5], using “browser navigations”, or having a “cutoff” [2]. But as Kovanovic et al. showed, the choice of the method or the cutoff time is not trivial and there is no best method for everyone [20]. They suggested exploring the data to find the cutoff or method that matches the dataset best. Amnueypornsakul et al. defined study sessions and used the actions and the sessions to calculate measures such as the length of the action sequence, the number of occurrences of each activity, and the number of Wiki page views [2]. Sheshadri et al. also defined study sessions based on the time difference between student actions and extracted measures such as the average number of actions in each session, inconsistency of the student (i.e. how different the number of the sessions started by a student is from the class average and how infrequent they get online), average length of sessions, and sessions including discussion forum activity [29]. While these features can add to the information collected directly from the online tools, they still do not consider transitions from one type of action to the other.

2.2 Sequence Analysis

2.2.1 Markov Models

Several methods have been used for analyzing the sequences of student actions. The first and most popular is the use of Markov chains and Hidden Markov Models. Jeong et al. for example, trained models based upon system logs of a learning-by-teaching system called Betty’s Brain in which the students learn material by teaching an artificial agent, Betty [14]. The possible student actions in this platform are reading the material they are trying to teach Betty; editing the material; using links and concepts in forms of adding, removing, or changing (e.g. link add); querying the agent by asking questions about the provided material; asking Betty the agent to explain the answer she just gave; and giving a quiz to assess how well Betty has learned. The authors extracted sequences of student actions on the platform and used a Hidden Markov Model to analyze their behavior. They found that students who generated better concept maps used balanced learning strategies that include moving between different actions, while the students who generated low scoring concept maps typically focused too much on getting the quiz answers correct. Faucon et al. used semi-Markov chains to model student activities in 61 MOOCs offered by EPFL university on Coursera and EdX platforms [8]. They utilized an Expectation Maximization algorithm for fitting the model and showed a graphical representation of their results on the transitions between different states (e.g. submission, forum participation, video watching, etc) for students of different behavior profiles. Similarly, Geigle et al. used clickstream data from a UIUC Text Retrieval MOOC on Coursera to generate a transition diagram between the different tools [10]. While Markov models are suitable for modeling student transactions between different states and are easy to visualize, the differences they show are often hard to quantify and compare between groups [14].

2.2.2 Sequence Clustering

Another approach for analyzing sequences of student actions is by clustering them. Desmarais et al. for example, collected the action logs of students in a college math learning environment [7]. In that work, they defined distinct sessions where the students paused for more than 5 minutes between them unless the action after the pause was a submission to an exercise, which might take longer. They then clustered the sequences using the Levenshtein distance and identified three types of sessions. The first was when the students showed exploratory behavior and engaged in a mixture of browsing through exercises and notes. The second type were the short sessions comprising a variety of behaviors such as browsing and attempting the exercises and quizzes. The third were exercise intensive sessions mostly consisting of exercise logs. Kizilcec et al. used a similar approach on the student engagements in a MOOC [17]. For each assessment period, they labeled the students as either “behind”, “on track”, “auditing”, or “out” based on their engagement with the course material. Then, they applied K-means clustering on the sequences of the student states in all assessment periods to identify the prototypical engagement patterns and were able to observe four clusters of students as completing, auditing, disengaging, and sampling.

A similar analysis was performed by Guerra et al. on data collected from QuizJET, which was a voluntary practice platform for students in an introduction to programming blended course [11]. They extracted the sequence of correct and incorrect submissions for each student and each question. Then, by comparing the sequences of different students to the sequences of the same student, they observed that these sequences are personal and can show people’s study approaches like a “study genome”. While these genomes were shown to evolve throughout the semester, the evolved genomes for a single user were still more similar than the genomes across different users. They were able to cluster the students based on their genomes and identify two groups as the confirmers and the non-confirmers. The confirmers kept trying examples of the same topic even after they got one correct, while the non-confirmers moved on to the next topic after they were able to solve one example correctly. Finally, Boroujeni et al. clustered student activities in a MOOC and were able to identify four user profile types: users who watch videos before making submissions (44% of the users), users who make submissions without watching videos (2% of the users), users who watch videos and never submit (7% of the users), and the users who change their habit in the semester (47% of the users) [4]. These categories are similar to the ones suggested by Kizilcec et al. [17]. While clustering seems to offer much insight on similar sequences and differences between different groups of students, it is often challenging to interpret these clusters and get to real world groups of students.

To account for the randomness in the generation of Markov Models, some researchers have generated Markov Models based upon each individual sequence and then clustered them to obtain more meaningful results. Köck et al. for example, designed an analysis pipeline which included a pre-processor which extracted activity sequences from the raw data, a modelling unit which converted the sequences into Deep Markov Models, and a final clustering unit [19]. They applied this pipeline to extract common transitions exhibited by different performance groups in a Physics course at the US Naval Academy. Similarly, Shih et al. applied the same clustering method on the Hidden Markov Models based on student activities in a Geometry Cognitive Tutor

[30]. Klingler et al. developed an evolutionary clustering pipeline to improve cluster stability over multiple training sessions in the presence of noise [18]. This pipeline extracts action sequences from log data, transforms them into per-session Markov Chains, computes pairwise similarities between students for every session, then performs clustering using evolutionary clustering, and uses the Akaike information criterion with correction (AICc) to select the best model. They suggested that this pipeline can be used as a black box on any ITS. While the combination of clustering and Markov Models might overcome some disadvantages of each individual, the results are still challenging to interpret as noted by Shih et al. [30].

2.2.3 Sequences as N-grams

Another approach often taken when analyzing students’ sequence data is treating the sequence of actions as a sequence of strings, and then identifying the common N-grams in it. Li et al. and Sinha et al. for example, extracted the sequences of actions for users in MOOCs and used the frequency of N-grams in such sequences as predictive features to predict students’ performance and certification [22, 31]. Maldonado et al. also performed a similar analysis on data extracted from an interactive tabletop (Digital Mysteries) and were able to identify frequent sequences of actions that distinguish between different performance groups [23]. Wen and Rosè applied this method to extract the most common types of sessions among students and were able to identify 4 types of sessions as lecture and peer assessment sessions, browse course sessions, assignment and forum sessions, final quiz and survey sessions, and lecture and quiz sessions [32]. Brooks et al. defined fixed duration sessions during the semester (i.e. 1 day, 3 days, 1 week, and 1 month) and recorded students’ activity in each frame as a binary feature [5]. They used frequent N-grams extracted from these sequences as features to make early and cross-class predictions of student dropout. While N-grams are easier to process since there are many available libraries for analyzing them, extracting information from them can still be challenging and require expert help at times.

2.2.4 Differential Pattern Mining

A newer approach which is mostly applied to ITS data is Differential Pattern Mining. The algorithms in this approach are able to identify patterns that are more frequent than a specific threshold and are significantly different between the two specified groups such as pass/fail students [1]. Kinnebrew et al. for example used a differential sequence mining algorithm to extract the sequences that are different between the high performers and low performers using the Betty’s Brain platform [15, 16]. They found that the high performers more frequently engaged in reading activities in a monitoring context, while the lower performers usually perform short reads mostly not relevant to their recent actions [16]. Herold et al. applied the same analysis to the sequences collected with LivescribeTMDigital pens, used to complete all of their homework and exams [13]. These pens are able to log students’ handwriting as time-stamped pen strokes providing the sequence in which it was written. Using this method, they were able to identify 98 patterns in total and use them to make predictions on the students’ performance in the closest exam after the task with an R^2 of 0.3. While this approach is able to make the differences in performance groups bolder, it is still relatively new, the libraries for it are limited, and it is also possible to end up with a large number of rules that will need clustering again.

3. DATASET

We collected data from two offerings each of two distinct courses, a Discrete Math course (DM) in the Fall semesters of 2013 and 2015, and a Java programming course (Java) in the Fall of 2015 and 2016. The 2015 offerings of these courses occurred contemporaneously. Both of these courses are core undergraduate courses, required for students majoring and minoring in Computer Science. They both use significant online materials and support and can be considered blended courses. The online materials include online assignments, supplemental material, and student forums.

In all these classes, Moodle is used as an LMS for providing the course material and the assignment descriptions to the students. Piazza is used as the discussion forum and the main resource for the students in these courses to ask questions and get answers from the teaching staff as well as to have discussions with their peers. The students were able to post completely anonymously for a brief time in DM-2013 but it was blocked in all other courses. Posting anonymously to other students was always allowed. Posting on Piazza was not required in any of these classes, but it was encouraged by the teaching staff as the best choice of asking for help. In the DM classes, the instructors used multiple answer questions on WebAssign for a large portion of the assignments. WebAssign was configured to allow the students to attempt each question several times to get it correctly and provides the students with instant automatic feedback on their answers. In the Java classes, the students use Github as a version control for keeping track of their code and editing in teams, as well as the means for submitting their code for grading. The students' Github repositories were connected to Jenkins servers, which ran several test cases on their code after each pushed commit. Some of the tests were predefined and authored by the instructional staff and some others were the tests designed by the students to test their own code. This enabled students to get instant feedback on their code and possibly revise it after each submission. Our datasets in this study consist of the Piazza discussions, Moodle logs, and final grades for all the classes as well as Github commit logs for Java classes and WebAssign logs for DM-2013.

While some of the tools used in these classes are different, they play similar roles in the classes. In the DM classes students use WebAssign to submit their assignments and to receive immediate automated feedback. And in this class they can re-submit as many times as they wish to get the right answer. Similarly, in the Java classes the students use Github for making submissions on their projects. While these submissions often take more time than answering a simple question on WebAssign, the students are still able to get immediate feedback from Jenkins and to try again. Consequently, while some visible trends in these classes might be different, we expect the trends for WebAssign and Github to be similar, because they play a similar role. Similarly, in both these classes, Moodle and Piazza can be considered as support platforms since the students can use the course material, project descriptions, and the questions on the forum to resolve their confusions. The types of support these platforms are offering are quite different, since asking questions on Piazza is a more direct means of asking for help than referring to the class material.

More information on the population of these classes is shown in Table 1. The grade distributions for these classes are shown in Figure 1. Both these courses are C-wall courses, where the students need a C or better in them to proceed to the next computer science courses in the curriculum. As shown in these

Table 1: Statistics of Each Class

Class	DM-2013	DM-2015	Java-2015	Java-2016
Total Students	251	255	181	206
Teaching Assistants	5	5	9	9
Instructors	2	2	4	4
Average Grade	81.2	87.6	79.7	79.9

figures, most of the students performed well in these classes. Thus, we decided that clustering them into pass/fail groups would be uninformative and result in a skewed dataset. Since the median grades for all these datasets were close to 90, the cutoff between an A- and a B+ in the courses, we decided to partition the classes into two groups, the *distinction* group earning an A- or above, and the *non-distinction* earning a B+ or below. This partitioning resulted in an almost even groups of the students. We believe that this segmentation leaves room for adjusting the analysis for other classes with different grade distributions.

Figure 1: The Distribution of Grades in Different Classes

3.1 Discrete Math

This course covered material such as propositional logic, predicate calculus, methods of proof, elementary set theory, the analysis of algorithms, and the asymptotic growth of functions. The total enrollments in these classes consisted of 251 students in DM-2013 and 255 students in DM-2015. Both of these classes were offered in two sections by two instructors with 5 shared teaching assistants. The average final grade in DM-2013 was 81.2 and 87.6 in the 2015 class. Both sections in each year shared the same Moodle page for assignments and class material, a Piazza forum for discussions, and both used WebAssign as well as hand-graded assignments. The only major difference between these two offerings was that in 2015 the instructor consciously delayed responding to posts on Piazza so that the TAs and other students would be more involved. However, most of the posts were still answered in a similar time frame to the ones in 2013 by the lead TA in that class.

3.2 Java Programming Concepts

The material of the Java class mainly consisted of software design and testing, encapsulation, polymorphism, inheritance, linear data structures, finite-state machines, and recursion. The total enrollment in these classes was 181 students with an average grade of 79.7 in 2015 and 206 students with an average grade of 79.9 in 2016.

Both of these classes were offered in two different in-person sections by two separate instructors as well as a distance education section by two other instructors, having a total of four

instructors with nine shared teaching assistants. We removed the data for the distance education students from our analysis since they were a much smaller group and differed substantially from the local students who could engage in face-to-face interactions. These classes used Piazza for discussions, Moodle for sharing course materials, Github for working on group projects, and Jenkins for automated code evaluation.

While the teaching material and the methods were mostly similar across both the offerings, there was a major difference in the lab structures for these classes. Both course offerings included lab sessions. In each session, the students completed a short assignment in a team of three with assistance from the teaching staff. One key difference between the course offerings was in the structure of the lab sessions. In 2015, the labs were conducted in 8 class sessions, thus engaging all of the students and the TAs simultaneously. In 2016 however, students were enrolled in separate lab sessions (approximately 24 students each) with a dedicated TA and participated in 12 lab sessions. Additionally, in 2015, students continued to work with the same peers for all lab assignments while in 2016, they rotated partners after every four tasks, thus giving them a chance to meet and work with a wider variety of people.

4. METHODS

4.1 Action Sequence Generation

We began by collecting the logs from Piazza, Moodle, Github, and WebAssign for the courses. Later, we merged them into a single class-level transaction file sorted by time. We then generated study sessions on student activities based on their online transactions as discussed in our prior work [29].

As Kovanovic et al. suggested, we decided to explore our data to find the best method for generating study sessions [20]. Since there was no specific time length for the student sessions in our data, we decided to use a set cutoff time, m , for defining the sessions. If two consecutive actions are less than m minutes apart, they belong to the same study session. Otherwise, that session ends and the second activity after m minutes is a start of a new session. We plotted the average time differences between sessions, the total number of sessions, and the average number of activities per session for different cutoff times. These plots showed us two points with major changes that were chosen as the cutoff times for “study sessions” and “browser sessions”. We chose 15 minutes as the cutoff time for browser sessions, which show the times that the students have been online for the entire session. We also chose 40 minutes as the cutoff time for study sessions, which allows the time for the students to go offline for coding or solving problems on paper and get back online. We used this gap between online actions of the students considering that they often work offline before committing their code to Github or solve a problem on paper before submitting an answer on WebAssign. In this work, we focused on study sessions since they showed more transitions between different platforms. The total number of sessions for each group in each class is shown in Table 2. In the end, we recorded the sequence of student actions in these sessions for further analysis.

Table 2: The Total Number of Sessions for Distinction and Non-distinction Groups in Different Classes

Class Name	Count in Distinction	Count in Non-distinction
DM-2013	7,697	6,533
DM-2015	6,574	3,434
Java-2015	12,219	12,786
Java-2016	19,913	9,829

Similar to Kinnebrew et al. and Maldonado et al., we decided to compact the action sequences [16, 15, 23]. For that purpose, we replaced consecutive occurrences of the same actions by the “+” notion (e.g. MMM was replaced with M+). Our prior work showed that 90% of the student sessions consisted of access logs to the same platforms [29]. Also, the nature of most of these platforms requires consecutive submissions, such as multiple commits to Github for solving issues or multiple submissions on WebAssign until they find the right answer and there is not much of a difference between asking a question on Piazza after 5 submissions or 6. Abstracting these repetitions helps us spot the transitions between these platforms more easily and spot more similar sequences among students.

4.2 Sequence Mining

In order to explain our methods, we first need to define the common terminology in sequence mining. Based on Agrawal et al., the “support” of a sequence is defined as the ratio of occurrences of that sequence among all the sequences in the data [1]. For example, if a sequence S has happened 10 times among a student’s study sessions and the student has a total of 100 occurred sequences, the support for S will be 0.1 for that student. Looking at the support metric helps us to look into what percentage of this student’s sequences are S , rather than how many occurrences of S this student has. It also simplifies the comparisons between high and low performing students, since generally, the number of all actions for high performing users are higher and this might stop us from spotting the major differences between the students from different performance groups.

Another term often used in sequence mining is ‘confidence’. Based on Agrawal et al., the confidence of the action B following the action A ($A \rightarrow B$) shows how likely it is for action B to occur after A and is defined as:

$$Confidence(A \rightarrow B) = \frac{Support(A \cap B)}{Support(A)}$$

To identify the most common patterns among the students, we applied the idea of N-gram analysis as in prior work [22, 5, 31, 32, 23]. In text mining, an N-gram of length N (e.g. bigram) refers to a specific sequence of N words. Many times, the frequency or the count of N-grams are calculated and used as features. In this work, we treated the sequences of student actions as lists of words and using Scikit-learn library in Python [26], for each student, we calculated the support for all sequences of lengths of 2 - 3 to represent the transitions between every two tools and also keep room to count for repetitions. Then, we collected these numbers for the distinction and non-distinction groups into two separate lists for each sequence. We extracted the average support percentage for each sequence in each group to find the most common patterns among them. Additionally, we performed Kruskal-Wallis (KW) ANOVA test between the two lists for all sequences to find the patterns that occur with a different distribution among these

two groups [21]. The Kruskal-Wallis test is a good choice in this context because it does not assume normally-distributed data.

Also, to determine how likely the students are to transfer to a system after using another, we used the Apriori algorithm provided in Apyori library in Python. This algorithm is used to mine frequent item-sets and association rules [1]. It takes a minimum required support and performs in an incremental order, starting with single items (i.e. 1-sequences) that meet the support requirement (L_1) and add other items to the set as long as the support meets the criteria (L_k). In this work, we set the minimum support to a low number (0.02) to be able to find and compare even the rare transitions and the 1-sequences were defined as single actions on each platform. Based on Agarwal et al. the pseudo-code for this algorithm is as below:

```

 $L_1$  = frequent 1-sequences

for ( $k=2; L_{k-1} \neq \emptyset; k++$ ) do
     $C_k$  = New candidates generated from  $L_{k-1}$ 

    for All possible sequences c do
        Increment the count of all candidates in  $C_k$  that are
        contained in c
    end for
     $L_k$  = Candidates in  $C_k$  with minimum support
end for
Answer = Maximal Sequences in  $\bigcup_k L_k$ 

```

To find the transitions often associated together, we applied the Apriori algorithm on the sequences from distinction students and non-distinction students and calculated confidence for the frequent ones.

While participation on Piazza was not mandatory, it was strongly encouraged by the instructors as the primary venue for help seeking in all of the courses. As a result, we would expect to observe a large number of transitions between the submission tools (i.e. WebAssign and Github) and Piazza. We also expect these transitions to be more frequent after students make consecutive submission attempts since students who struggle with assignments often make several tries before contacting the instructors. We also expect higher-performing students to make more of such transitions because seeking help when they are struggling, rather than postponing it for later or going without, will help them to perform better in the course.

5. RESULTS

Since the tools used in these systems are different, we will present our results in each part for each class separately.

5.1 RQ1. What are the most common transitions between different course tools?

5.1.1 DM-2013

Our prior study on this class had shown that 90% or more of the student sessions are focused on a single tool and the sessions consisting of all WebAssign actions was the most common across them [29]. As Table 3, shows, consistent with our prior work, the most common sequence for both performance groups is repeated WebAssign Submissions, covering on average 70% of action sequences. This is not surprising due to the fact that the

students had unlimited submissions on this platform and often sought to “brute force” the answers.

The next most frequent pattern in both groups is multiple Moodle actions, which is again a unsurprising as students are required to log in on each session and must often navigate to their desired resources through a series of actions. Interestingly, transitions between WebAssign and Moodle are also comparatively frequent (the most frequent kind of transition between tools), consisting of approximately 4% of the total sequences. The more common transitions would be some submissions on WebAssign and moving to Moodle, while this sequence sometimes gets repeated several times as students move between these two tools and we can observe sequences like “w+m+w” on average in 0.4% of the students’ transitions or even more complicated ones such as “m+w+mw+”. Such transitions show students moving between class material like slides and the assignments and may show them referring to slides to revise their answers on WebAssign. We need to note that the sequences longer than 3 actions were not counted towards the calculation of support and confidence and thus, are not shown in the tables.

One would expect struggling students to move between WebAssign and Piazza to ask questions about the submissions, but as our results show, this transition does not happen frequently. Even among better performing students, it is more common to go to Moodle than Piazza after a couple of submissions, but it is even less likely for the lower-performing students. It seems like the students prefer to find the answers to their confusion among class material rather than asking questions or they prefer to leave help-seeking for another session.

Table 3: The Support for the Most Frequent Sequences in DM-2013 (W = WebAssign, M = Moodle, P = Piazza)

	Avg in Distinction	Avg in Non-distinction
W+	0.7064	0.7227
M+	0.1408	0.1615
W+M, M+W, MW, WM	0.0429	0.0380
P+	0.0303	0.0133
P+W, W+P, PW, WP	0.0039	0.0006
P+M, M+P, PM, MP	0.0004	0.0001

To better understand the student transitions between WebAssign and Moodle or WebAssign and Piazza, we calculated the confidence score for sequences in which Moodle and Piazza actions occur in the same session after one or more WebAssign actions. The results of the Apriori algorithm for this class are shown in Table 4. As we can see, there is almost a 10% chance of the students going to Moodle after one or more WebAssign submissions, while there is less than a 1% chance of them going to Piazza.

Table 4: Confidence for Different Transitions from WebAssign in DM-2013 (W = WebAssign, M = Moodle, P = Piazza)

	Distinction	Non-Distinction
$W \rightarrow M$	0.11	0.09
$W \rightarrow P$	0.007	0.003
$W+ \rightarrow M$	0.11	0.09
$W+ \rightarrow P$	0.007	0.003

5.1.2 DM-2015

The most frequent sequences for this class are shown in Table 5. Unfortunately, in this class, we do not have access to the WebAssign data. Thus, there were far fewer patterns found in this data than the 2013 class. But as with the prior offering,

the Piazza actions seem to be not nearly as common as Moodle actions. Additionally, the transitions between Moodle and Piazza were rare.

Table 5: The Support for the Most Frequent Sequences in DM-2015 (M = Moodle, P = Piazza)

	Avg in Distinction	Avg in Non-distinction
M+	0.913	0.966
P+	0.081	0.034
PM, MP, M+P, P+M	0.003	0.000

5.1.3 Java-2015, Java-2016

The most frequent sequences for these classes are shown in Table 6. These classes are similar to DM-2015 in that consequent Moodle actions is the most common sequence with an average about 55-65% of students' sequences in 2015 and about 70-80% of the student sequences in 2016. While in these classes Github commits are similar to WebAssign activities in DM-2013, the findings show that the students tend to commit their changes far less frequently than they submit questions on WebAssign. Multiple commits on Github are the next most frequent and they occur in about 20-30% of the student sequences in 2015 and 10-15% of sequences in 2016. Similar to DM-2013, where the students often moved between the submission system and the course material on Moodle, in these classes 4-6% of the student sequences are moving between Github and Moodle, where only 0.1-0.5% of the sequences refer to moving between Github and Piazza. In these classes also, moving back and forth a few times between the platforms is observed and we can see sequences such as "g+m+g+m" or "g+mg+m+g".

Table 6: The Support for the Most Frequent Sequences in Java Classes (G = Github, M = Moodle, P = Piazza)

	Avg in Distinction	Avg in Non-distinction
Java 2015		
M+	0.566	0.655
G+	0.294	0.204
G+M, M+G, GM, MG	0.041	0.043
P+	0.011	0.010
P+M, M+P, MP, PM	0.004	0.003
P+G, G+P, PG, GP	0.003	0.003
Java 2016		
M+	0.698	0.782
G+	0.134	0.089
G+M, M+G, GM, MG	0.062	0.052
P+	0.012	0.005
P+G, G+P, PG, GP	0.005	0.001
P+M, M+P, MP, PM	0.003	0.002

As with the DM-2013 class, we calculated the confidence score of action sequences that include Moodle and Piazza in the same session after one or more of Github actions. The results of the Apriori algorithm for these two classes are shown in Table 7. As we can see, there is a 28-37% chance of the students going to Moodle Github submissions, while there is only less than a 3% chance of them going to Piazza.

As our results show, the students seem more likely to go to the project descriptions or the course material after some submissions on Github rather than the discussion forum.

Table 7: Confidence for Different Transitions from Github in Java classes (G = Github, M = Moodle, P = Piazza)

	Distinction	Non-Distinction
Java 2015		
$G \rightarrow M$	0.31	0.36
$G \rightarrow P$	0.03	0.03
$G+ \rightarrow M$	0.31	0.37
$G+ \rightarrow P$	0.03	0.03
Java 2016		
$G \rightarrow M$	0.28	0.31
$G \rightarrow P$	0.02	0.007
$G+ \rightarrow M$	0.32	0.34
$G+ \rightarrow P$	0.02	0.01

5.2 RQ2. Which transitions are significantly different between the distinction and non-distinction groups?

5.2.1 DM-2013

The KW p-value results for the support percentages of different sequences in DM-2013 class is shown in Table 8. The significant values with $p < 0.05$ are marked as bold, while edge cases with $p < 0.1$ are marked in italics. We only included the significant and edge-case patterns and the transitions between platforms in the table. As these results show, the distinction students are significantly more likely to have a sequence of Piazza actions than the non-distinction group, with an average of 3% of their activities in the distinction group compared to 1% in the non-distinction group. The distinction students are also more likely to go to Piazza after a repetition of other activities than the non-distinction group. While the transition between WebAssign and Moodle (W+M, WM, M+W, MW) is high in both groups and not significantly different, the distinction group is more likely to move between Piazza and WebAssign (PW, WP, W+P, P+W) on average 0.4% compared to 0.01%.

Table 8: KW p-values between distinction and non-distinction students for different sequence supports in DM-2013 (W = WebAssign, M = Moodle, P = Piazza)

N-gram	Avg in Distinction	Avg in Non-distinction	KW pvalue
+P	0.0018	0.0001	3.31E-03
P-W transitions	0.0039	0.0006	3.08E-03
P+	0.0303	0.0133	1.30E-05
M-W transitions	0.0429	0.0380	0.644608

5.2.2 DM-2015

The KW p-values for the different sequences between the distinction and non-distinction group are shown in Table 9. Similar to the previous offering, the distinction group in this class is also more likely to have consequent Piazza activities, as well as go to Piazza after consequent actions on another platform. They are also more likely to move between Moodle and Piazza, while the non-distinction group is more likely to perform consequent actions on Moodle.

Table 9: KW p-values between distinction and non-distinction students for different sequence supports in DM-2015 (M = Moodle, P = Piazza)

N-gram	Avg in Distinction	Avg in Non-distinction	KW pvalue
P-M transitions	0.003	0	1.93E-03
+P	0.001	0	<i>5.82E-02</i>
M+	0.913	0.966	5.80E-05
P+	0.081	0.034	1.18E-04

5.2.3 Java-2015

The KW p-values for the different sequences between the distinction and non-distinction groups are shown in Table 10. Similar to the prior classes, the distinction group in this class was also more likely to go to Piazza after consequent actions on other platforms. Also, similar to DM-2015, the transitions between Moodle and Piazza are significantly more likely among the distinction group. Also, the distinction group has significantly more consequent actions on Github than the non-distinction group. However, while on average more sequences have a repetition of Piazza activities among distinction students, this difference is not significant in this class. Similarly, moving between Github and Moodle is more likely on average among the non-distinction group, but this difference is also not significant.

Table 10: KW p-values between distinction and non-distinction students for different sequence supports in Java-2015 (G = Github, M = Moodle, P = Piazza)

N-gram	Avg in Distinction	Avg in Non_distinction	KW pvalue
M+	0.566	0.655	0.046
P-M transitions	0.004	0.003	0.022
+P	0.003	0.002	<i>0.052</i>
P+	0.011	0.010	<i>0.095</i>
G+	0.294	0.204	0.005
G-M transitions	0.041	0.043	0.788
P-G transitions	0.003	0.003	0.336

5.2.4 Java-2016

The KW p-values for the different sequences between the distinction and non-distinction groups are shown in Table 11. Similar to the previous classes, in this class also we observe more repetitions of Piazza activities in the distinction group as well as more Piazza activities after a repetition of activities on other platforms. Also, similar to the 2015 Java offering and DM-2015, the non-distinction group is more likely to have consequent actions on Moodle. Despite the other classes, transitions between Github and Moodle as well as Github and Piazza are significantly different in this class and more likely for the distinction group. Comparing these results to the ones in Table 7, the findings seem conflicting since the non-distinction group is more likely to have Moodle activity in the same session after Github activities. However, we need to note that the Apriori algorithm, unlike N-grams, calculates the possibility of Moodle actions occurring after, but not necessarily consequently after, the Github activities. So, it seems like that the non-distinction group are more likely to move to Moodle at some point of the session after Github activities, but less likely to do so consequently after the Github actions.

Table 11: KW p-values between distinction and non-distinction students for different sequence supports in Java-2016 (G = Github, M = Moodle, P = Piazza)

N-gram	Avg in Distinction	Avg in Non_distinction	KW pvalue
M+	0.6976	0.7822	1.30E-05
+P	0.0021	0.0010	1.97E-02
P+	0.0123	0.0048	1.12E-03
G-M transitions	0.0616	0.0521	3.98E-02
P-G transitions	0.0046	0.0010	3.20E-04
P-M transitions	0.0026	0.0023	0.53

6. DISCUSSION

While the classes we analyzed and the offerings within them differ in topic, materials, structure, and instructor approach, our analysis shows that there are common patterns across all of them.

The first visible pattern is that the students are much more likely

to complete consecutive actions on the platform they are already using rather than switching to another platform. In all of the classes, the most common trend is two or more actions on WebAssign followed by Moodle in DM-2013, and Moodle followed by Github in the Java classes, while repetitions of Piazza actions seem to be more rare, even compared to platform switches. This might be due to the fact that most of the activities on Moodle, Github, and WebAssign consist of a sequence of smaller actions. For example, the students are much more likely to solve several problems on WebAssign or attempt a single problem several times, rather than only making a single attempt and leaving the platform. Similarly, on Moodle, the students often need more than one click to reach the material they need to access and on Github, the students are likely to push their code, face a failing test on Jenkins, and make a new commit to solve that issue. However, the actions on Piazza are not as closely monitored. On this platform, only making posts and replies are logged and viewing the posts or replies are not. Thus, the students are much more likely to make a single post or reply without any other visible actions on this platform and that might be a reason why consecutive Piazza actions are not as common as the other tools.

Another common pattern is that in contrast to our expectations, the students in all of the classes were much more likely to go back to the class material and the assignment descriptions on Moodle rather than rely on the discussion forum after one or more tries on their assignments. This was illustrated by the high confidence for transitions from WebAssign and Github (i.e. the submission systems) to Moodle (i.e. the indirect support platform), compared to transitions from these platforms to Piazza (i.e. the direct support platform), even in the higher performing students. As we expected, the visible trends for WebAssign and Github are similar in these classes due to the similarity in their educational role. As mentioned before, since the views are not monitored on Piazza, it is therefore possible that in some cases the students do refer to Piazza posts, only to find their answers in another student's question, without making any posts or replies. Thus, the lower amount of transitions to Piazza might be due to this difference in recording the activities. However, the teaching staff often found that the students did not look for their questions in their peers' posts and kept asking similar questions.

While both the performance groups have a large amount of consecutive Moodle actions, the non-distinction groups have on-average more of such sequences and this difference is often significant in these classes. Also, having repetitive Piazza actions and going back to Piazza after two or more actions on another platform is, on average, more common between the distinction students and this difference is significant in most of the classes, while in other classes an edge case that could be significant if we considered $p < 0.1$. This shows that while the non-distinction group seems to insist on finding the answer among the class material (or possibly reading the existing posts on Piazza), the distinction group seems to ask or answer questions on the discussion forum more often.

7. CONCLUSIONS

While multiple researchers have applied sequence analysis to educational data, most of this research has been focused on ITS data or MOOC data and there is not much research on the transitions of students between several resources in blended courses. In this study, we gathered logs from several online platforms that students interacted with in two offerings of two

undergraduate courses. We extracted sessions of studies among these activity logs and analyzed the sequences of the student actions in these sessions to find the general patterns in student transitions as well as the patterns that distinguish between the higher performing students and low-performers.

Our results show that consequent actions on the same platform are more likely for the students. Additionally, students are more likely to refer to the class material and the assignment descriptions rather than the discussion forum after a couple of submissions on assignments. However, the higher performers generally had more transitions between platforms and were often more likely to go to the discussion forum than the non-distinction group. We also found that even though some platforms used in classes are different, the results can be generalized across classes as long as the tools play similar educational roles, as WebAssign and Github did in our case. This can help findings to be expanded across a variety of courses using different platforms.

The results of this study can also help instructors identify helpful and harmful patterns among students and offer suggestions for forming more productive habits. The frequencies of these sequences added to the previously defined behavioral features can also help researchers improve the performance of their prediction models on student performances.

One limitation of this study is the differences between the length of the activities and how they are recorded on the different tools. Some types of activities are shorter and thus, more likely to repeat, such as WebAssign submissions where the questions are often multiple answers and quick to submit, while some other activities take a longer time, such as writing a Piazza post or solving an issue with the code and making a new commit. Additionally, while Moodle platform logs every action the users make online, Piazza only records the posts and replies and not the views. These differences in the tools might affect our findings. Further analysis, such as considering the time between actions differently for different tools might help us understand the trends in student activities better. Also, the WebAssign action logs are not available for the DM-2015 class, which limits the findings for this class and makes the comparisons between the two DM offerings less significant. Adding later similar offerings of these courses to the study in the future might help in finding more consistent trends.

In the future, we plan to expand the study to use different sequence analysis tools, such as the differential sequence mining tools. Those tools might be able to highlight other differences among the performance groups that are more difficult to spot using the current tools. Also, replicating our analysis on other courses and more offerings of the same courses can give us a better insight on how general some of these findings are. In the end, we plan on extracting predictive features from the student transitional patterns and add them to the other behavioral features to improve the accuracy of the performance prediction models on students, make the models fit better across classes, or make them fit better for earlier predictions in the semester.

ABSTRACT

Student's academic performance prediction empowers educational technologies including academic trajectory and degree planning, course recommender systems, early warning and advising systems. Given a student's past data (such as grades in prior courses), the task of student's performance prediction is to predict a student's grades in future courses. Academic programs are structured in a way that prior courses lay the foundation for future courses. The knowledge required by courses is obtained by taking multiple prior courses, which exhibits complex relationships modeled by graph structures. Traditional methods for student's performance prediction usually neglect the underlying relationships between multiple courses; and how students acquire knowledge across them. In addition, traditional methods do not provide interpretation for predictions needed for decision making. In this work, we propose a novel attention-based graph convolutional networks model for student's performance prediction. We conduct extensive experiments on a real-world dataset obtained from a large public university. The experimental results show that our proposed model outperforms state-of-the-art approaches in terms of grade prediction. The proposed model also shows strong accuracy in identifying students who are at-risk of failing or dropping out so that timely intervention and feedback can be provided to the student.

Educational data mining, graph convolutional networks, deep learning, attention

1. INTRODUCTION

Higher educational institutions face major challenges including timely graduation and retention of enrolled students. The National Center for Education Statistics (NCES) reports that the six-year graduation rate for first-time and full-time undergraduates is around 60%; the retention rate among first-time and full-time degree-seeking students is

around 80% [1]. These alarming statistics require higher educational institutions to take actions to improve their effectiveness and efficiency at educating students. Machine learning techniques have been increasingly developed and applied to educational settings in the hope of improving students' learning and increasing students' success [3, 26, 16]. Many systems and applications have been proposed; such as course recommender systems [7], academic trajectory and degree planning [20], educational early advising systems [9], and knowledge tracing for intelligent tutoring systems [35, 22]. Developing methods for accurate modeling and predicting students' performance is the key to these systems and applications.

Traditional performance prediction methods can be categorized into two types. The first builds a static model, which takes a feature vector as input (such as a student's grades in previous courses or student-related features) and outputs the predicted grades. A common approach that belongs to this category is linear regression methods [23]. Students take courses sequentially, i.e., they take some courses at each semester; and their performance in courses taken in the next semester depends on courses taken in previous semesters. Further, their knowledge evolves by taking a sequence of courses. To capture the temporal dynamics of students' knowledge evolution, sequential models have been proposed. A set of representative approaches within this category use recurrent neural networks (RNN) [12, 11].

Undergraduate degree programs are designed in a way that knowledge acquired in prior courses serves as prerequisites for future courses. The knowledge and skills required to do well in a course are acquired in multiple prior courses. The knowledge dependence between courses exhibit complex graph structure as shown in Figure 1. Figure 1 shows the prerequisite structures for computer science and civil and infrastructure engineering degree programs at George Mason University. Each node represents a particular course. An edge pointing from one course to another shows the prerequisite relationship. As an example, to do well in the data structure course (CS310), students need to acquire programming skills, object-oriented programming knowledge (CS211) and math (MATH113) which come from multiple different courses. The graph in Figure 1 also shows hierarchical relationships where a course can depend on another course which is at a much lower academic level. In addition to the prerequisite structures, degree programs are flexible, i.e., students can choose to take elective courses based on their interests and

Qian Hu and Huzefa Rangwala "Academic Performance Estimation with Attention-based Graph Convolutional Networks" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 69 - 78

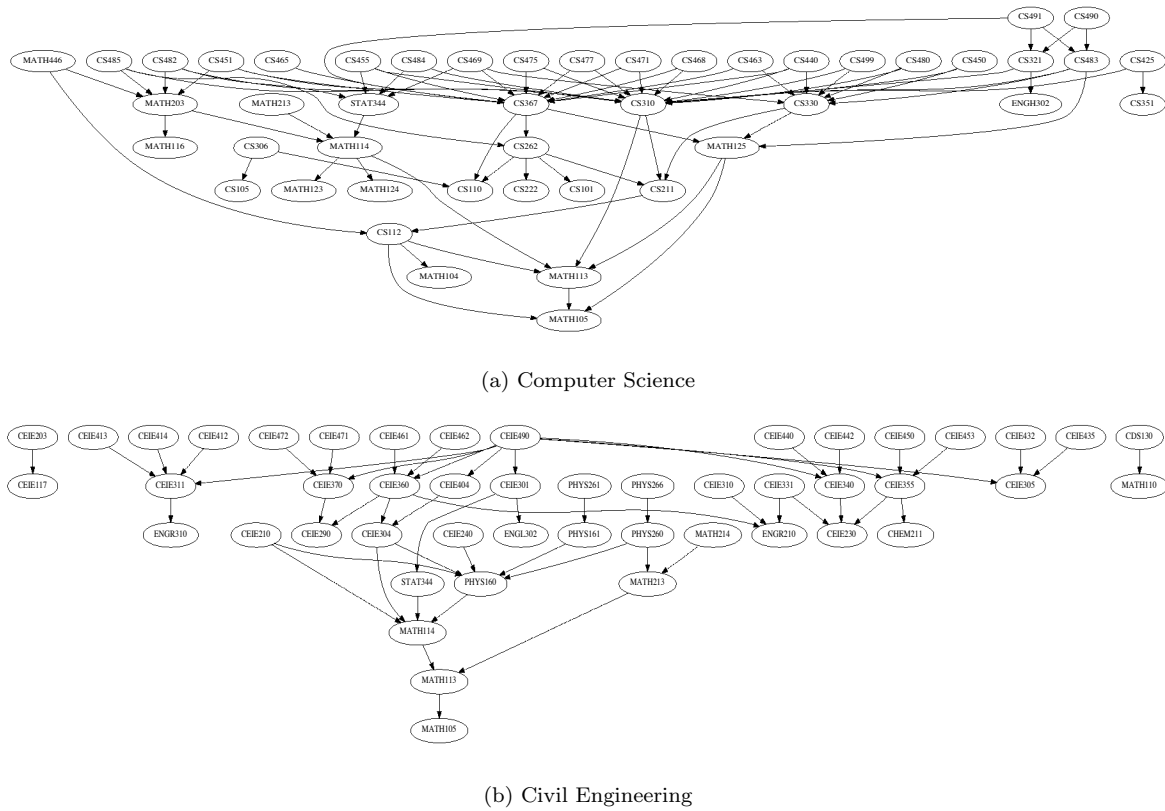

Figure 1: Course dependence structure in two representative majors.

Figure 2: Comparison of Three Types of Model Architectures. In this example, a student takes course C_1, C_2, C_3 in the first semester, course C_4, C_5 in the second semester, course C_6, C_7 in the third semester before takes the target course C_T .

do not have to follow a specific ordering when taking these courses.

The complexity and flexibility of the degree programs make predicting students’ performance a challenge task. Prior approaches usually simplify or ignore these complex dependencies. Figure 2 shows the comparison of three types of models. Figure 2a shows a static model, where a student’s performance is directly dependent on a set of prior courses. Figure 2b shows a sequential model, where students’ knowledge evolution is partially modeled. To overcome the constraints and limitations of the traditional models, we propose a model based on graph convolutional networks to capture the complex graph-structured knowledge evolution exhibited by students’ data. Specifically, we propose an attention-

based graph convolutional network (ACGN) model for predicting a student’s grade in a future course. Figure 2c shows the graph model, where each course depends on all courses taken in the semester before it so that students’ knowledge evolution is fully captured.

When a system is used for decision making e.g., as a support tool for advisors to identify students who are at-risk of failing courses they will take; it is essential for the predictions to be interpretable. This allows the stakeholders to trust the decision making systems and make informed decisions. We show that our attention-based model is able to provide an interpretable and useful explanation for the predictions. Our model is able to analyze a student’s performance in prior courses and identify a collection of important prior courses

to explain the student’s performance in target course.

We performed extensive experiments on real-world datasets to evaluate our model and compare it with the other two types of models aforementioned. The experimental results are consistent with our observations that models with architectures more close to the degree program have better modeling capability and prediction performance. One of the important applications for students’ performance prediction is early warning and advising systems, where at-risk students are first identified and timely support is provided to improve their academic success. The experimental results show our model’s effectiveness at identifying at-risk students.

The key contributions of the paper are summarized as follows:

- Flexible graph structured model for students’ academic performance prediction. Observing the complex structures of undergraduate degree programs, we propose a graph convolutional network model for students’ performance prediction.
- Attention based model for explanation. Providing explanations for a model’s predictions makes the model useful for decision making. Our attention-based model can explain the predictions by identifying a set of prior courses important for the predictions.
- Identification of at-risk students. While most models achieve good performance at predicting students’ performance, they suffer from low accuracy at identifying at-risk students. Our proposed model is able to achieve comparable performance with state-of-the-art models.

2. RELATED WORK

The need to improve higher education services and offerings has attracted research on developing methods for predicting students’ performance [4, 27]. In this section, we review related work on students’ performance prediction. The related work can be classified into three categories: (i) static models, (ii) sequential models and (iii) graph models.

2.1 Static Models

Static grade prediction models learn a mapping function, where input is student-related features and the output is predicted grade. Polyzou et al. [23] proposed regression models specific to courses or students for predicting a student’s grade in a target course. They found that focusing on a course specific subset of the data leads to more accurate predictions. Elbadrawy et al. [8] introduced a personalized multi-regression model for predicting students’ performance in course activities. Compared to a single regression model, this model is able to capture personal student differences. To understand how students’ behavior impacts their academic performance, Wang et al. [32] collects students’ behavioral data using smart phone for performance prediction. Many other classic supervised learning approaches have been used for students’ performance prediction including decision trees [2], support vector machines and neural networks [31].

Adapted from recommender systems domain, matrix factorization [14] approaches are popular for grade prediction.

These factorization approaches make the assumption that a student’s knowledge/skills and a course’s knowledge components can be jointly represented with latent vectors (factors) [30]. Polyzou et al. [23] proposed course-specific matrix factorization models for grade prediction that decompose a course-specific subset of students’ grade data. The student course records also exhibit grouping structures and a domain-aware matrix factorization model was developed for the joint course recommendation and grade prediction [7]. Ren et al. [25] proposed matrix factorization model coupled with temporal dynamics for grade prediction.

2.2 Sequential Models

Students take courses sequentially. Their knowledge and skills evolve by taking a series of courses. To model the temporal dynamics of students’ knowledge evolution, sequential models have been proposed. Balakrishnan [5] proposed a Hidden Markov Model for predicting student dropout by modeling students’ activities over time in a Massive Open Online Courses (MOOCs). Swamy et al. [29] models student progress on coding assignments in large-scale computer science courses using recurrent neural networks. Kim et al. [12] proposed a bidirectional long short term memory (BLSTM) model for the online educational setting. Hu et al. proposed course-specific markovian models for students’ grade predictions [10]. Morsy et al. proposed cumulative knowledge-based regression models for next-term grade prediction, which models students’ knowledge evolution by using a sequential regression model. Hu et al. [11] proposed long short term memory models for grade prediction in traditional higher education.

2.3 Graph Neural Networks Models

Deep learning approaches have found unprecedented success in a myriad of applications involving regular structured data such as images (grids) and text (sequences) [18]. Graphs are more complex and irregular than grids or sequences and recent research efforts involve designing deep learning models for graph data. Graph neural networks have been proposed and applied to many areas such as computer vision for point clouds classification [33], action recognition [34]; recommender systems [6] and traffic prediction [19]. To the best of our knowledge, there is no prior work on students’ performance prediction using graph neural networks.

3. METHODS

3.1 Problem Statement

Given a student s , the set of courses taken and grades obtained in term t are represented by \mathbb{P}_s^t . For a sequence of terms $1 \dots T_s$, we denote $\mathbb{P}_s^{1 \sim T_s} = \mathbb{P}_s^1, \mathbb{P}_s^2, \dots, \mathbb{P}_s^{T_s}$ to represent the sequence of courses taken and grades obtained by student s in T_s terms. For a target course c taken in the future (next) term, the objective of the proposed method is to predict the grade student s will achieve in course c denoted by \hat{g}_s^c .

The proposed models are trained in a course specific manner i.e., for each target course c we learn a unique model. Due to the flexibility of academic degree programs, in each semester different courses can be taken; and for each student, the number of semesters studied before taking the tar-

Figure 3: The proposed model.

get course will be different. Therefore, we index the length of the sequence with student-specific variable T_s .

For every target course c , a subset of frequently taken prior courses are identified from all the prior courses taken by students who have already taken the target course c . These prior courses are denoted as C_c of size N_c . For student s , only the prior courses in C_c are extracted from $\mathbb{P}_s^{1 \sim T_s}$ to form a graph which is represented by an adjacency matrix $\mathbf{A}_s^c \in \{1, 0\}^{N_c \times N_c}$ and a feature matrix $\mathbf{F}_s^c \in \mathbb{R}^{N_c \times D}$, where D represents the number of features. Take Figure 2c as an example, the student takes courses c_1, c_2, c_3 in the first term, c_4, c_5 in the second term and c_6, c_7 in the third term; we want to predict his/her grade in course C_T . Adjacency matrix \mathbf{A}_s^c for this student represents his course taken process. Courses taken in the current term are fully connected to courses taken in the next term; 1 represents connected, 0 otherwise. A row of the feature matrix \mathbf{F}_s^c represents the student's grades in corresponding prior courses.

3.2 Model Description

Figure 3 shows an overview of the proposed model. It is composed of three parts: 1) graph convolutional network, 2) attention layer and 3) a fully connected layer.

3.2.1 Graph Convolutional Network (GCN)

Convolutional neural networks (CNNs) show superior performance on several applications related to vision [15], speech and text [17]. CNNs are powerful because of their ability to exploit feature locality at multiple granularity. Graph Convolutional networks have a similar working mechanism but on data with more complex structures, namely, graph.

The input to a GCN is an adjacency matrix \mathbf{A}_s^c and feature matrix \mathbf{F}_s^c , encoding student s 's course taking process and grades in prior courses, respectively. Multiple layers of graph convolutional layer are applied on \mathbf{A}_s^c and \mathbf{F}_s^c to learn a graph level embedding $\mathbf{Z}_s^c \in \mathbb{R}^{N \times D}$. Each row of \mathbf{Z}_s^c corresponds to a node embedding vector. A graph convolutional layer is mathematically described as follows:

$$\mathbf{H}^{(l+1)} = f(\mathbf{H}^{(l)}, \mathbf{A}) = \sigma(\tilde{\mathbf{D}}^{-\frac{1}{2}} \tilde{\mathbf{A}} \tilde{\mathbf{D}}^{-\frac{1}{2}} \mathbf{H}^{(l)} \mathbf{W}^{(l)}) \quad (1)$$

where $\tilde{\mathbf{A}} = \mathbf{A} + \mathbf{I}_N$ is the adjacency matrix with self-connections, $\tilde{\mathbf{D}} = \sum_j \tilde{\mathbf{A}}_j$ is the normalization matrix, $\mathbf{H}^{(l)}$ is the input and $\mathbf{W}^{(l)}$ is the weight matrix to be learned. $\mathbf{H}^{(0)} = \mathbf{F}_s^c$ and $\mathbf{H}^{(L)} = \mathbf{Z}_s^c$; namely, the input into the first GCN layer is the feature matrix \mathbf{F}_s^c , the output from the last GCN layer is the student-specific graph embedding \mathbf{Z}_s^c .

A filter in convolutional neural networks aggregates information from a pixel's neighbors. Similarly, the graph convolutional layer aggregates information from a node's neighboring nodes and generates a new node embedding vector by the following equation

$$\mathbf{h}_i = \sigma(\sum_j \frac{1}{c_{ij}} \mathbf{h}_j \mathbf{W}) \quad (2)$$

where node j is node i 's neighbor. A higher level of the node embeddings are generated by applying multiple GCN layers. Multiple layers of GCN aggregate information from a node's further neighbors. As shown in Figure 3, the first GCN layer aggregates information from a node's direct neighbors, namely, in our case the courses taken in last semester. The second layer collects information from a node's second degree neighbors, i.e., the courses taken two semesters ago. The final output is the graph embedding which entails information from all the courses a student has taken.

3.2.2 Attention Layer

The output from GCNs is a graph-level embedding matrix, which encodes information about a student's knowledge and skills acquired in prior courses. The knowledge acquired from different prior courses has different importance for the target course. To capture the importance differences of the prior courses, we integrate attention layer into our model. Attention mechanism allows the model to focus on the relevant features or information useful for prediction. It works by computing an importance score [24], higher score means the corresponding prior course is more important for pre-

dicting a student's performance; given by

$$e_i = MLP(\mathbf{h}_i) \quad (3)$$

$$\alpha_i = \frac{\exp(e_i)}{\sum_{k=1}^N \exp(e_k)} \quad (4)$$

where MLP is a learnable function, i.e., multi-layer perceptron, α_i is the attention score corresponds to \mathbf{h}_i . The output from the attention layer is an attention score vector α .

The graph embedding matrix \mathbf{Z}_s^c is weighted by attention scores to form a weighted graph embedding matrix $\mathbf{Z}_s'^c$ given by

$$\mathbf{Z}_s'^c = \begin{bmatrix} \alpha_1 \mathbf{z}_{s,1}^c \\ \vdots \\ \alpha_i \mathbf{z}_{s,i}^c \\ \vdots \\ \alpha_N \mathbf{z}_{s,N}^c \end{bmatrix} \quad (5)$$

Finally, the pooling layer coarsens the weighted graph embedding matrix into a latent vector \mathbf{v}_s^c . The latent vector is passed through a multilayer perceptron; the output from which is the predicted grade.

$$\hat{g}_s^c = f(\mathbf{v}_s^c) \quad (6)$$

where f is a multilayer perceptron network.

4. EXPERIMENTAL PROTOCOL

4.1 Dataset Description

Table 1: Dataset Statistics

Major	Fall 2017			Spring 2018		
	#S	#C	#G	#S	#C	#G
CS	5,042	16	47,889	5,297	20	52,152
ECE	1,992	18	34,355	1,980	18	34,170
BIOL	7,065	20	52,574	6,976	20	52,672
PSYC	5,367	20	25,207	5,368	20	25,247
CEIE	2,222	17	30,956	2,181	16	30,283
Overall	21,688	91	190,981	21,802	94	194,524

#S total number of students, #C number of courses for prediction, #G total number of grades

The data is collected at George Mason University from Fall 2009 to Spring 2018. The five largest majors are chosen including: 1) Computer Science (CS), 2) Electrical and Computer Engineering (ECE), 3) Biology (BIOL), 4) Psychology (PSYC) 5) Civil Engineering (CEIE). The evaluation procedure is designed in a way to simulate the real-world scenario of predicting the next-term grades. Specifically, the models are trained on the data up to term $T - 2$ and validated on term $T - 1$ and tested on term T . The latest two terms are chosen as testing terms, i.e. term Fall 2017 and term Spring 2018. For example, to evaluate the performance of the models on term Fall 2017, the model is trained on data from term Fall 2009 to term Fall 2016, validated on term Spring 2017 to choose the parameters associated with different approaches and finally tested in term Fall 2017. The statistics of the datasets are listed in Table 1

4.2 Evaluation Metrics

We evaluate the models from two perspectives: 1) the accuracy of grade predictions, 2) the models' ability at detecting at-risk students.

To evaluate the models' accuracy of grade prediction, two evaluation metrics are used a) mean absolute error (MAE) and b) percentage of tick accuracy (PTA).

$$MAE = \frac{\sum_{i=1}^N |g_i - \hat{g}_i|}{N} \quad (7)$$

where g_i is true grade and \hat{g}_i is predicted grade.

In the grading system, there are 11 letter grades (A+, A, A-, B+, B, B-, C+, C, C-, D, F) which correspond to (4, 4, 3.67, 3.33, 3, 2.67, 2.33, 2, 1.67, 1, 0). A tick is the difference between two consecutive letter grades. The performance of a model is estimated by how many ticks away the predicted grade is from the true grade. For example, the tick error between B and B is zero, B and B+ is one, B and A- is two. To use PTA for evaluation, we first convert the predicted numerical grade to its closest letter grade and then compute the percentage of errors with 0 tick, within 1 tick, and within 2 ticks denoted by PTA₀, PTA₁, and PTA₃, respectively.

We also evaluate the models' performance of identifying at-risk students. At-risk students are defined as those whose grades are lower than 2.0 (C, C-, D, F). The predicted grades below 2.0 are treated as positives and above 2.0 are treated as negatives. The process of detecting at-risk students is similar to grade prediction except that the output from the model (the predicted grade) is converted to 1 or 0 based on whether the predicted grade is below or above 2.0. As the number of at-risk students is low, we use F-1 score as evaluation metric.

4.3 Comparative Methods

Bias Only (BO)

Bias only method only takes into account a student's bias, a course's bias and global bias[23]. The predicted grade is as follow

$$\hat{g}_s^c = b^c + b_s^c + b_{c'}^c \quad (8)$$

where b^c , b_s^c , $b_{c'}^c$ are global bias, student bias and course bias, respectively.

Course Specific Matrix Factorization (CSMF)

The key assumption underlying this model is that students and courses can be jointly represented by low-dimensional latent factors. N , M and D is the number of students, courses and latent dimension, respectively [23]. To predict a student's grade in a course, we have:

$$\hat{g}_s^c = b^c + b_s^c + b_{c'}^c + \langle \mathbf{u}_s^c, \mathbf{v}_{c'}^c \rangle \quad (9)$$

where b^c is global bias, b_s^c is student bias term, $b_{c'}^c$ is course bias term; \mathbf{u}_s^c is student s 's latent vector, $\mathbf{v}_{c'}^c$ is course c 's latent vector.

Course Specific Regression (CSR)

Course specific regression (CSR) [23] is a linear regression model. The input into this model is a vector \mathbf{x}_s^c representing a student's grades in prior courses. A course specific subset

of prior courses included in $\mathbb{P}_s^{1 \sim T_s}$ are flattened to form the vector \mathbf{x}_s^c . The predicted grade is

$$\hat{g}_s^c = w_0^c + \mathbf{x}_s^c \mathbf{w}^c \quad (10)$$

where w_0^c is bias term and \mathbf{w}^c are weight vectors to be learned.

Multilayer Perceptron (MLP)

Multilayer Perceptron is a generalized version of CSR. CSR model is a linear model, which is not able to capture non-linear and complex patterns in students' grades data. Therefore, multilayer perceptron has been proposed by [11] for grade prediction. Similar to CSR, the input \mathbf{x}_s^c is a student's grades in prior courses.

$$\hat{g}_s^c = f(\mathbf{x}_s^c) \quad (11)$$

where f is the model to be learned.

Long Short Term Memory (LSTM)

Figure 4: LSTM for grade prediction

Long short term memory (LSTM) is an extension of recurrent neural networks (RNN) for modeling sequential data. The assumption of using LSTM for students' performance prediction is that students knowledge and skills are evolving by taking courses in each semester. To capture the temporal dynamics of students' knowledge evolution, LSTMs have been proposed in [11]. The input $\mathbf{x}_{s,t}^c$ at time step t is a student's grades in courses at semester t . Many to one architecture is utilized and the output from the last step of LSTM is fed into a fully connected network; the output from which is the predicted grade. The model architecture is shown in Figure 4, where the courses a, b, c, d, e are prior courses, $\mathbf{x}_{s,t}^c$ encodes the student's grades in courses at time t and the output \hat{g} is the predicted grade.

4.4 Implementation

Our method is implemented in Pytorch [21]. For model optimization we use Adam [13]. To avoid model overfitting, we used l_2 norm regularization (with coefficient 0.001) and dropout (dropout rate 0.05) [28]. The number of dimensions for the graph embedding is chosen from a list of (8, 12, 16, 20, 32, 64).

5. EXPERIMENTAL RESULTS

5.1 Grade Prediction

Table 2 reports the performance of ACGN and comparative approaches for the task of next-term grade prediction for the Fall 2017 and Spring 2018 semesters using the MAE metric. The proposed ACGN model achieves the best performance in most cases except the Civil Engineering (CEIE) major. The CEIE major has relatively simpler knowledge dependence structure as shown in Figure 1b. A majority of higher level courses, such as 300 and 400 level courses for the CEIE major have shallow knowledge dependence. While for CS major, the higher level courses have deeper knowledge dependence or longer pre-requisite chains.

Another observation is that models which are able to capture the complex knowledge dependence more have better performance. The static models (BO, CSMF, CSR, MLP) are outperformed by sequential model (LSTM) in most cases, on average by 9.2%; the sequential model is outperformed by graph model (ACGN), besides CEIE major, on average by 7.0%. The experimental results are consistent with our assumption that the knowledge dependence in the undergraduate degree programs is complexly networked structures and a graph model is well-suited at capturing the underlying dynamics.

Table 3 shows the comparative performance using the percentage of tick error accuracy. In contrast to MAE, the PTA metric can provide a fine-grained view of the errors made by different methods. From Table 3 we observe that the performance gap between models at \mathbf{PTA}_0 is larger than at \mathbf{PTA}_2 . For example, for CS majors in Fall 2017, the gap between the best performing model ACGN and the worst performing model BO at \mathbf{PTA}_0 is 13.24%, which is larger than 8.53% at \mathbf{PTA}_2 .

5.2 Detecting At-risk Students

Detecting at-risk students early is a fundamental task for early warning and advising systems. We evaluate the models' performance at detecting at-risk students. Table 4 shows the experimental results evaluated by F-1 score. The percentages of at-risk students in different majors are presented at the table footnote. The PSYC major has the lowest percentage of at-risk students. The experimental results show that LSTM and ACGN achieve the best performance at detecting at-risk students. BO performs worst at the detection of at-risk students. BO only captures the average performance of a student and a course, which is biased by other students and courses' performance and the average performance of other students and courses is usually higher than 2.0 (the threshold of defining at-risk students).

5.3 Interpretation with Attention

Machine learning models have achieved impressive performance in many tasks. However, most of them remain black boxes and there are concerns about their transparency. A model's capability to provide explanations for its predictions can increase its transparency. For decision making, understanding the reasons behind predictions can help decision makers make informed decisions. Grade prediction models serve as an assistant tool for advisors to make decisions on whether to intervene on a student or not. When the model

The percentage of at-risk students for each major in Fall 2017 is CS (23.7%), ECE (18.9%), BIOL (25.8%), PSYC (8.3%), CEIE (15.9%); In Spring 2018, it is CS (23.7%), ECE (24.7%), BIOL (18.1%), PSYC (6.6%), CEIE (14.1%).

predicts that a student is at-risk of failing a course, knowing which prior courses results in the prediction can also help advisors provide personalized feedback to students.

Attention mechanism works by letting the model focus on important information for prediction. In our proposed model, the design of the attention layer lets the model focus on important prior courses. The output from the attention layer is a vector of scores representing the importance of the prior courses computed by Equation 4. In this section, we show by case studies how the attention scores from the attention

layer explain the model’s predictions, especially, why the model predicts that a student is at-risk of failing a target course.

Table 5 shows four case studies. We keep the most important prior courses identified by attention score. For the first case study, the target course is CS-310, the student’s true grade in the target course is F and the predicted grade is C-. The most important four courses identified by attention layer is MATH-212, MATH-125, CS-262, CS-211. The reason for predicting this student as at-risk is that the stu-

Table 5: Case Studies By Attention Score

Target Course	True Grade	Predicted Grade	Prior Courses	Grades	Attention Score
CS-310	F	C-	MATH-213	N	0.33
			MATH-125	N	0.33
			CS-262	N	0.33
			CS-211	C	0.01
CS-310	D	D	MATH-213	F	0.913
			MATH-114	C	0.072
			CS-211	N	0.015
BIOL-311	F	C	BIOL-213	C+	0.5315
			BIOL-214	C+	0.4685
BIOL-452	D	C	CHEM-211	C+	0.5271
			BIOL-214	B	0.2784
			BIOL-213	C	0.1945

N means that the student did not take the course. Courses in bold mean they are in prerequisites chain.

dent did not take MATH-212, MATH-125, CS-262, therefore lacks the necessary knowledge to do well in the target course. In the second case, the student's true grade in CS-310 is D, the predicted grade is D. The three most important courses are MATH-213, MATH-114, CS-211. The reason for predicting this student as failing the target course is that he failed MATH-213 and did not do well in MATH-114 and did not take CS-211, which is the prerequisite of the target course. In the third case, the student's true grade in the target course is F and the predicted grade is C. The two most important prior courses identified are BIOL-213 and BIOL-214, both are in prerequisite chain of the target course and the student did not do well in them. The fourth case shows that the student failed the target course BIOL-452 and the predicted grade is C. The three most influential prior courses are CHEM-211, BIOL-214, BIOL-213. Courses CHEM-211 and BIOL-213 are in prerequisite chain and the student did not perform well in them.

From the case studies, we can see that the attention layer identifies missing knowledge components for a target course, arising due to two reasons: 1) the student did not take some important prior courses, 2) the student did not do well in the corresponding prior courses.

5.4 Sensitivity Analysis

In this section, we evaluate the sensitivity of the model's performance with respect to the dimension of the graph embedding. In Figure 5, the x-axis is the embedding dimension and y-axis is MAE for Fall 2017 and Spring 2018 datasets. From Figure 5, we can see that the model's performance varies with the dimension size. Overall, its performance is quite stable across the different majors.

6. CONCLUSIONS

Students' performance prediction is a fundamental task in educational data mining. Predicting students' performance in undergraduate degree programs is a challenging task due to several reasons. First of all, undergraduate degree programs exhibit complex knowledge dependence structures. Secondly, undergraduate degree programs are flexible which means students can take courses without following specific order and they can choose to take whatever electives they are interested in. Traditional approaches like static and sequential models are not able to fully capture the complexity

Figure 5: Sensitivity analysis on embedding dimension.

and flexibility of students' data.

In this work, we proposed a novel attention-based graph convolutional networks for students' performance prediction. The model is able to capture the relational structure underlying students' course records data. We performed extensive experiments to evaluate the proposed model on real-world datasets. The model is evaluated in several aspects: 1) grade prediction accuracy and 2) ability to detect at-risk students. The experimental results show that our model outperformed state-of-the-art approaches in terms of both grade prediction accuracy and at-risk students detection. Finally, the attention layer provides explanations for the model's prediction, which is essential for decision making.

ABSTRACT

We explore generalizability and fairness across sociodemographic groups for predicting on-time college graduation using a national dataset of 41,359 college applications. Our features include socio-demographics, institutional graduation rates, academic achievement, standardized test scores, engagement in extracurricular activities, and work experiences. We identify five latent classes based on available sociodemographic data and train Random Forest classifiers to successfully predict 4-year graduation. When individually trained and tested on each class using a split-half validation method, we achieved AUROCs between 0.629 and 0.694. We then evaluate how a model trained on the entire dataset performs on each latent class by performing a slicing analysis, finding a 6 to 10 percent improvement in AUROCs compared to the individual-class models. We explore fairness of our model by extending the slicing analysis to consider Absolute Between ROC Area (ABROCA), finding similar values for each of our latent classes. We contemplate how our results might be used to avoid perpetuating biases inherent in college application data.

college success, college applications, generalizability, fairness, slicing analysis, National Student Clearinghouse, Common App

1. INTRODUCTION

In 2016, the Obama administration issued a report urging data scientists to explore “how technologies can deliberately or inadvertently perpetuate, exacerbate, or mask discrimination.” [6]. To this point, in recent years, machine learning has come to influence a range of real-world activities, such as detecting credit fraud, financial investing, advertising, and, of course, education.

Stephen Hutt, Margo Gardner, Angela L. Duckworth and Sidney D'Mello "Evaluating Fairness and Generalizability in Models Predicting On-Time Graduation from College Applications" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 79 - 88

These methods make complex, sometimes life changing, decisions based upon training data, often without considering if the training data is biased. This is a critical omission because training data takes advantage of past events, which may be unfairly biased against certain subpopulations, such as those of a particular race, gender, or sexual orientation. Given that the past data may be biased, machine learnt models further perpetuate or even exacerbate these biases. The resultant models can be described as ‘unfair’ because they treat different subpopulations differently. For example, Amazon recently had to decommission their recruitment AI as it favored male applicants for technical jobs [15], ostensibly because in the ten years of hiring data used to train the model, the company had predominantly hired more men than women in technical roles. This biased training data caused the model to negatively evaluate resumes that alluded to the applicant being female (e.g. containing the phrase “women’s chess club captain” or having attended a women’s college).

In the context of education, there has been considerable interest in predicting a range of educational outcomes, such as affect, learning style, likelihood of dropping out of a course, and whether a student will succeed on an upcoming test [18, 46]. In this paper, we examine generalizability and fairness in the specific case of predicting college success. We use the CommonApp-NSC dataset, a 6-year longitudinal de-identified dataset of college application data and graduation outcomes. We first identify five subgroups of applicants based on sociodemographics and then train Random Forest classifiers to predict on-time college graduation from application data. We explore how the models generalize across groups and how fair the models are to each of the groups.

1.1 Background

A college degree offers a wide variety of personal, academic, and economic benefits [3]. For example, 2015 median earnings for young U.S. adults (25-34 years of age) with a Bachelor’s degree were 64% higher than those who had only completed high school, a consistent pattern over the past 15 years [39]. In addition to economic gains for the student, college completion also correlates with economic gains for the nation as a whole [11].

However, based on the latest data, only 40% of first-time, full-time U.S. students graduated with a Bachelor’s degree within four years [41, 52] (60% graduated within six years). Moreover, the academic

achievement gap separating students by race/ethnicity in K12 persists in college. Only 21% of Black and 30% of Hispanic students graduated within 4 years, compared to 44% White and 48% Asian/Pacific Islander students [52].

These numbers suggest that there is considerable room for improvement overall and especially for closing the achievement gap. More to the point of the present focus, they introduce a substantial potential for bias in any machine learning model which uses demographics to predict 4-year college graduation outcomes since these models might inherently predict lower graduation for an underrepresented minority based on historic rates irrespective of their abilities.

In addition to demographics, socioeconomic (SES) factors have been reliably linked to college success [16, 17, 19, 63]. An early 1964 study showed that SES factors such as family income, parental occupation, and parental education levels had a significant effect on college retention and graduation [22]. Other work has reported similar links between SES and college success [1, 34, 60], particularly with respect to the relationship between SES and ethnicity [48]. This signals another potential for bias. Indeed, recent work in machine learning (and even in the popular press) has called for an examination of how SES is used in models [14, 67], especially when making crucial decisions about a person's future.

Beyond SES, academic achievement such as high school GPA and standardized test scores have also been shown to be predictive of college success. In large scale studies [53, 66], including a landmark study with 150,000 students, both standardized test scores and high school GPA predicted college success. However, both of these measures has also been (negatively) linked to SES [54, 68], suggesting potential bias in a more indirect way.

Beyond sociodemographics and cognitive ability, Goodwin and Hein [28] hypothesize that the "X-Factors" such as a can-do attitude, self-discipline, and good study habits are also important for college success. This view aligns with Duckworth [16], Dweck [19], Walton [63], and others who argue that non-cognitive factors such as grit, self-control, mindset, and social belonging [16, 17, 19, 63] are critically important for college success after accounting for sociodemographics and cognitive ability.

One complicating factor is that these non-cognitive traits are difficult to accurately measure. Therefore, admissions counselors must rely on self-reports or informer reports (such as from teachers), which have a number of known biases (see [17] for a review). To address this, there is an interest in more objective measurement approaches. One relevant proxy measure of non-cognitive traits is sustained engagement in extracurriculars during high-school. The rationale for the predictive value of extracurriculars is that they provide a context for the development and demonstration of key non-cognitive characteristics (e.g., initiative [37], identity [21, 37], competence, confidence, and character [9]) linked to academic success. However, extracurriculars might also be inherently biased, in that SES influences the amount and types of available extracurricular opportunities [31, 38]. There is some evidence that work experiences might provide similar benefits as extracurriculars provided youth do not work too much (see [65]). However, low SES students might be the ones more likely to work [61, 64], suggesting that work experiences might also be a biased proxy measure.

In previous work with the CommonApp-NSC data set [33], we trained models that could successfully predict four year graduation using sociodemographics, cognitive ability, and non-cognitive factors. However, we did not consider how our models generalized

between subpopulations or if a population was being treated unfairly. We address this issue here by exploring how the models perform across different sociodemographic groups and evaluate the fairness of our classification methods.

1.2 Related Work

Because the field of generalization is vast [59], we focus specifically on generalization across sociodemographic groups in the context of education. We then go on to discuss fairness for a model – that is whether predicted outcomes for a particular group are consistently negative. Available techniques fall into two groups: (1) methods for evaluating if an existing model is fair; and (2) methods for developing a fair model. Both approaches are discussed here.

In machine learning, cross-validation is performed to improve the likelihood of a model generalizing to new instances, or in educational data mining, to new students (i.e., students not in the training set). However, what about generalizability beyond the student to groups of students? The results might not be so promising. For example, a review by Blanchard [7] indicated that work in intelligent tutoring systems (ITS) and artificial intelligence in education (AIED) overwhelmingly samples from White, educated, industrialized, rich, and democratic (the so-called WEIRD) countries. Blanchard notes that cognitive factors differ greatly across cultural contexts and stresses the importance of expanding research in ITS and AIED to non-WEIRD countries.

Baker and Gowda [4] showed that generalizability is not even guaranteed within communities in the United States of America. Using data from a diverse group of students interacting with an ITS, they found that behaviors that were predictive of disengagement significantly differed between urban, suburban, and rural students. This was further supported in [42], where models trained on urban or suburban students generalized to each other but not to rural students. In contrast, Samei et al, [49] reported that their models of effective classroom discourse generalized across urban and non-urban classrooms. Bosch et al [8] also have had success with generalizability. In work on detecting affect while students interacted with an educational physics game, they found that video-based affect detection generalized across ethnicity (as perceived by human observers) and gender.

Each of the aforementioned approaches explore generalizability by training models on one group and testing on another, a simple yet effective method of validation. However, this approach does not apply when it is infeasible to build models for each sub population, for example, when training data is limited. In this case, we must instead consider how a model trained on all the data performs to individual subgroups of interest. In slicing analysis [50], predictive models are trained on the entire data set and evaluated by "slicing" along subpopulations of interest (such as race, or ethnicity). This allows a researcher to explore if a model is only successful for a certain group (e.g. if a model trained on all data is only accurate for white students).

Gardner et al. [26] recently presented a metric to evaluate fairness within slices. They propose Absolute-Between-ROC Area (ABROCA) for quantifying how a predictive model's performance varies across different student subgroups. This metric evaluates whether a model privileges (provides more accurate classification) or disparately impacts (provides less accurate classification) a subgroup by comparing the group's ROC curve to the ROC curve of a baseline group. In a study analyzing MOOC dropout rate, they show a significant difference in privilege given to males versus

females in machine learnt models across a variety of feature sets and across a classification techniques.

Another method for evaluating models is Individual Fairness [20], which states that in order for a model to be considered fair it must yield similar predictions to similar individuals. The success of this evaluation method depends upon how similarity is defined, a challenging task when the number of predictors is large as in any complex prediction problem.

An alternative to evaluating fairness post-hoc is to design fair models from the ground up. *Fairness through unawareness* posits that a model is fair if it does not include any protected (potentially biased) variables (e.g. [25, 36]). However, this approach ignores the fact that protected variables such as ethnicity may be encoded (via correlation or similar) with variables not initially considered to be protected, such as participation in extracurricular activity or standardized test scores. [27, 32].

Alternatively, Kusner et al. [36] have introduced the idea of Counterfactual Fairness, which requires an understanding of causality among predictors (see [36, 45]). Whereas this method has been successful in datasets with a limited number of variables, understanding causality in a complex dataset presents many challenges and may render this approach unfeasible.

1.3 Contributions of Current Study

The present study is novel in multiple respects. We build upon work predicting on-time Bachelor's graduation solely from information contained in college applications. We derive 143 variables from each application and train models on 41,359 instances. Our sample includes students from all 50 U.S. states as well as international students, yielding many options for exploring generalizability and fairness.

We first cluster the sociodemographic data by identifying latent classes of students within the dataset. From available sociodemographic variables (e.g., race/ethnicity, parent education, parents' marital status, and English language learner status), we identify five distinct latent classes of applicants for further investigation. Specifically, we examine the accuracy of models trained and tested on the same class. We then use a slicing analysis to investigate how a model trained on all the data performs for each of the classes.

It should be noted that our complex, real-world dataset does not easily lend itself to current methods for designing fair models. Decades of research have shown that SES is a predictor of college success (as cited above), so a fairness through unawareness approach would require ignoring an important predictor. Likewise, counterfactual fairness requires understanding causality in the dataset, a challenge given that we are working with 143 variables. We instead evaluate the fairness of models trained with traditional machine learning approaches using ABROCA as the pertinent metric.

2. DATASET

2.1 CommonApp-NSC Data¹

The Common App [55] is a nonprofit organization that hosts a portal where high school students can complete and submit applications to nearly 700 colleges. The Common App streamlines the admissions processes by enabling students to complete one "common" application that can be submitted to multiple colleges

across the country. Whilst individual colleges may have their own supplemental applications (e.g. additional essays), the core application remains the same.

The Common App has three parts. The student section includes information on sociodemographics, future college plans, family history, academic history, standardized test scores, honors received (for academic, sporting, or other pursuits), extracurricular activities, work history, and disciplinary history. Students also submit a personal essay, but these are not available to us due to privacy concerns. A separate evaluation consists of teacher ratings of the student across several dimensions, ranging from "quality of writing" to "reaction to setbacks". Finally, the secondary school report contains information on the student's high school (e.g., percent of graduation class enrolling in college), the student's academic performance (e.g., class rank, GPA), and evaluations from the student's guidance counselor (e.g., ratings of academic achievements, difficulty of courses, and personal qualities).

The National Student Clearinghouse (NSC) is a nonprofit organization created in connection with the financial aid lending industry that gathers enrollment data for student borrowers. The NSC data tracks the following information for each student on a per-semester basis: college name, college type (2/4 year; private or public), enrollment (none, full, part-time), major, and graduation status (degree, and major).

Both organizations have merged, de-identified, and shared the data with us, which we prepared for statistical analyses. The Common App contains individual applications from 413,675 students who completed the 2008 application for admission in the 2009 school year. We successfully matched 362,205 of these applications to 2015 NSC records. From this subset, we removed 50,894 students who enrolled in college prior to 2008 and an additional 3 students due to data integrity issues, leaving 311,308 students.

To account for institutional effects on the probability of graduation, we obtained 4- and 6-year graduation rates from the National Center for Educational Statistics (NCES) [47] for the institution students first enrolled in (i.e., their first entry in the NSC). We used 2012 graduation rates to avoid including students from our 2009 student cohort who would be on-track to graduate with a 4-year degree in 2013. We obtained institution graduation data for 89% of the students, resulting in a reduced sample of 278,201 students.

We also obtained information on students' high school environments (e.g. demographics of the school) from the NCES data [47], using the 2007-2008 school year to avoid direct overlap with our student cohort.

Our data only included applications/reports that were completed online, as there was a paper option in 2008. Of the 278,201 students, only 41,359 had a corresponding teacher evaluation and secondary school report, which contained critical GPA scores as entered by guidance counselors. We presume that a majority of the missing cases were submitted on paper; they were therefore not available to us. Previous work investigated the importance of GPA in predicting college success [33] and found that it did not significantly boost prediction after accounting for the other features. Here, we with this subset for consistency, but do not consider GPA.

¹ In what follows, we provide an abridged description of the dataset, which was originally published in [33].

2.2 Encoding the Application

We extracted 143 features from the application, including auxiliary sources (e.g., NCES data), which we grouped these into the following categories:

Personal and family, 48 features. Features in this category focus primarily on sociodemographics (e.g., ethnicity, sex, number of parents who went to college, etc.).

Academics and standardized tests, 38 features. This category encodes information from the ‘academics’ (e.g., did a student intend to graduate from high-school on time) and ‘standardized tests’ (e.g., SAT scores) section of the student application along with data about the high school environment from the NCES (e.g., teacher-student ratio).

Activities and work experience, 45 features. Students enter information for up to seven extracurricular activities, including the type of the activity, the time commitment, and the school years in which they participated in the activity. In addition, students can enter up to three work experiences, from which we derived features such as number of jobs and hours per week at each job.

Honors, 10 features. Students describe academic and sporting honors received during their high school career. For each honor, we encode the type of honor, the level of the honor (school, state, national or international), and the grade when it was received.

Institutional graduation rates, 2 features. These are the 4- and 6-year graduation rate of the colleges in which students first enrolled.

Our sample of 41,359 students represented all 50 states and included some international students. The students represented 5,678 secondary schools and were enrolled in 1,238 post-secondary institutions. Forty-four percent (44%) graduated within four years of enrollment; this rate aligns with national norms [41].

2.3 Student demographics

Our sample was majority female (56%). Student age was unavailable due to data de-identification, which eliminated birth dates. With regard to ethnicity, 54% of students identified as Caucasian, 8% as African American, 8% as Hispanic, 8% as Asian American, 5% as Asian Indian, 4% as Mexican American, 1% as Native American/Alaskan, and 5% as other ethnicities (students could select multiple ethnicities as well as decline to answer). In terms of home life and education, 96% had two living parents, 77% of students reported living with both parents, 68% had two parents who attended college, and 16% had one parent who attended college. For secondary education, 68% of students reported attending a public high school, 14% a religious high school, 16% an independent high school, 2% a charter school, and 1% were home schooled. The subset of 41,359 students was representative of the full sample of 311,308 students, differing only with respect to the number of parents who attended college [33].

3. LATENT CLASS ANALYSIS

We used latent class analysis (LCA) to identify five clusters of students based on individual sociodemographic characteristics (race/ethnicity, parent education, parents’ marital status, and English language learner status), the race/ethnic composition of students’ high schools (% African American, % Latino, % White, and % Asian American), and whether the school was Title I eligible (a school is eligible if it has high concentration of low income students [23]). We selected these characteristics because they not only paint a relatively comprehensive portrait of socioeconomic status, but also have demonstrated associations with college success (see Introduction). Specifically, White and Asian American

students, students of college educated parents, students with married parents, and students who speak English as a first language have higher on-time graduation rates than are African American and Latino students [58], first generation college students [57], English language learners [35], and students with single parents [44, 51]. Likewise, high schools with large percentages of low-income and minority students, when compared to predominantly White higher-income high schools, often have lower rates of college matriculation and completion [29]. Although often used in generalizability studies (e.g., [8, 24]), we did not include gender in these models as it does not relate to SES and ethnicity (see Discussion).

We used the entire sample size, in this case, all students who attended a public high school ($N=216,133$) for the latent class analysis in order to obtain the most representative clusters. We used complex mixture models with a maximum likelihood estimator in MPlus 7 [40] to identify our latent class structure. Standard errors were adjusted to account for the clustering of students within high schools. An initial two-class solution yielded AIC and BIC values of 385,195.512 and 385,493.737, respectively. Subsequently, we tested solutions with up to six classes. Although each increase in the number of classes resulted in notable improvements in model fit (see Table 1), the magnitude of these improvements diminished with increasing model complexity. The selection of the final five-class solution (see Table 2) balanced model fit against pragmatism. Specifically, the six-class solution fit the data somewhat better than the five-class solution, but two of the six classes had very similar profiles (i.e., profiles similar to class 3 in Table 2). Each class in the five-class solution, on the other hand, had a distinct profile as described below.

Table 1. Model fit by number of latent classes

#	AIC	Incremental reduction in AIC	BIC	Incremental reduction in BIC
2	385195.51	--	385493.74	--
3	196766.61	188428.90	197198.52	188295.21
4	16127.75	180638.87	16693.35	180505.18
5	-103474.54	119602.29	-102775.26	119468.60
6	-180815.24	77340.70	-179982.27	77207.01

Of the 41,359 students analyzed here, only 28,122 were included in the LCA analysis since we only focused on those who attended a public high school. Class 1 contains a plurality of Black students with a sizable white minority (20%) in their high schools. The majority of students are native English speakers, approximately half of students are first generation college students and approximately half of students are children of unmarried parents. This reflects an average SES. Class 2 contains a plurality of White students, but other groups are represented in their high schools (51% white). The majority are native English speakers with married, college-educated parents. Students in this class typically attend a non-Title I eligible, diverse high school where approximately half the students are white with moderate representation across other ethnic/race groups. Thus, this class can be categorized as predominantly white students, high SES students in diverse high schools. Class 3 is similar to Class 2, except with a higher majority of white students and students typically attending a primarily white high school. These students are also high-SES.

Table 2. Five Class Solution: profiles across classification variables by latent class N= 28,122

Latent class/ label	N	Proportion of class that is...										Average high school race/ethnic proportions			
		Proportion of sample					First generation			Attending Title I eligible high school					
		White	Black	Latino	Asian	Other race/ethnicity	college student	married parents	Child of English Language Learner	high school	high school	White	Black	Latino	Asian
1 (Black, mid-SES)	1,745	0.06	0.26	0.10	0.08	0.10	0.52	0.54	0.14	0.40	0.40	0.20	0.61	0.12	0.03
2 (White/diverse, high SES)	5,670	0.20	0.47	0.10	0.13	0.15	0.33	0.75	0.18	0.25	0.25	0.51	0.15	0.18	0.11
3 (White, high SES)	16,959	0.60	0.69	0.02	0.04	0.07	0.23	0.79	0.05	0.20	0.20	0.85	0.04	0.04	0.03
4 (Asian, high SES)	1,051	0.04	0.17	0.02	0.05	0.67	0.10	0.87	0.52	0.20	0.20	0.28	0.05	0.13	0.52
5 (Latino, low SES)	2,697	0.10	0.17	0.11	0.54	0.13	0.70	0.62	0.45	0.77	0.77	0.13	0.12	0.65	0.06

*Note. Proportions of students of varying race/ethnic groups in each class do not sum to 1 due to missing data. N is less than the full sample as we only included students from public high schools

Class 3 is the largest of the classes representing 60% of the students. Class 4 is the smallest of the classes, containing 4% of students, the majority of students are Asian, and a sizable number (52%) of students are English language learners. The majority of students in class 4 have college educated; married parents and attend a non-Title I eligible high school, which suggests high-SES. Finally, in class 5, there is a plurality of Latino students, many (45%) of whom are English language learners. The majority of students have married parents who did not attend college. Most students in this class attended majority Latino, Title I eligible high schools, suggesting low-SES.

4. MACHINE LEARNING

We used the scikit-learn library [43] for machine learning. We focused on Random Forests because previous work that considered logistic regression, naive Bayes, decision tree (using the scikit-learn CART-like algorithm), and gradient-boosted decision trees [33]. found that Random Forest was consistently the best performing approach.

Hyperparameters for the random forest classifier [10, 30], were tuned on the training set using the cross-validated grid search method provided by scikit-learn [43]. Specifically, the number of trees in the forest (`n_estimators`), the maximum number of features to consider when searching for the best split (`max_features`), and the maximum depth of the trees (`max_depth`) were tuned. By careful tuning of these hyperparameters, we negate the need for traditional feature selection, as this is then implicit in the Random Forest algorithm when hyperparameters are set to appropriate values. The random seed was set to a random integer generated by the Numpy.random library [62]. Other hyperparameters relating to limiting the size of the trees (other than maximum depth) were left at default values as resources were sufficient to compute unpruned trees in reasonable time.

We validated our models using a student-level k-fold cross-validation ($k=2$). For each iteration of the classifier, a random 50% of students were assigned to the training set, the remaining 50% to the test set, the process was repeated with the sets reversed, and results computed after pooling predictions across the folds. By using a low k value, we increase the size of our test set, increasing the likelihood that successful models will generalize to new data. This process was repeated for 15 iterations and the results were averaged across iterations. We selected 15 iterations to balance computation time and reliability across multiple training/testing pairs. Although setting $k=2$ imposes a stringent test of the model by removing half the data for the test set, it helps to ensure that the models will generalize to new students.

We note that for some of the latent classes there is a substantial data skew (more instances of not graduating than graduating). Class imbalance poses a challenge because supervised learning methods tend to bias predictions towards the majority class. To compensate for this concern, we used the SMOTE algorithm [12] to create synthetic instances of the minority class by interpolating feature values between an instance and its randomly chosen nearest neighbors until the classes were equated. SMOTE was only applied on the training sets; the original class distributions were maintained in the test sets in order to ensure validity of the results.

5. RESULTS

We report area under the receiver operating characteristic curve (AUROC). Whereas overall recognition rate/model accuracy is susceptible to data skew, AUROC presents the result relative to chance (0.5).

5.1 Generalization

We first compared how models trained on each class individually compared to a model trained upon all data. The all data model was evaluated using a slicing analysis, where predictive model performance is evaluated by “slicing” along subpopulations, in this case, the computed LCA classes. We trained a random forest classifier on all of the data (41,359 instances) and then evaluated it by the five latent classes previously identified. The results of this analysis are shown in Figure 1 with the baseline reflecting chance performance (AUROC of 0.5).

Each of the individual models performed above chance, suggesting that our methods generalized across classes. However, there was a disparity between the classes, the highest performing (class 3, white high SES) performed 10% better than the lowest performing (class 4, Asian high SES). The two lowest AUROC scores were for class 1 (Black, Mid SES) and class 4 (Asian, high SES); the two classes with the lowest number of instances (1,745 and 1,051 respectively).

Our model trained on all students performed better across all classes than individually trained models, with improvements ranging from 6-10%. The difference between the worst performing and best performing groups also decreased to 6%, implying better generalization across groups. One reason for this may be the improved power that comes with a higher number of instances; the all data model was trained on 41,369, instances, more than double that of the largest LCA class (16,959 instances).

Figure 1. Accuracy of individual models compared to a slicing analysis of a classifier trained on all data

5.2 Fairness

We next examined the fairness of our model. Using the model trained on all data (41,359 instances) we computed five ROC curves, one for each of the latent classes. Recall that this was done for 15 iterations with $k=2$ cross validation. The ROC curves for a single iteration is shown in Figure 2, this iteration was chosen as the ABROCA scores are similar to the averages shown in Table 3. A sixth ROC curve for all students is also shown for comparison.

In order to formally compare two curves, we use Absolute Between ROC Area (ABROCA) [26], defined as:

$$\int_0^1 |ROC_b(t) - ROC_c(t)| dt$$

Here, ROC_b is the baseline curve and ROC_c is the comparison curve. ROC curves characterize model accuracy as the likelihood of correct positive predictions versus the likelihood of false positive predictions. ABROCA measures the absolute difference between two curves, allowing for the possibility that the curves may cross each other (see [26] for details). A higher ABROCA value between two groups implies a higher difference in predictions and thus more unfairness in the model.

Figure 2. Sample ROC curves for each Latent class from model trained on 41,359 instances

We used class 3 (White, high SES) as the baseline ROC curve as it is the highest performing group in our dataset. It is also a group typically overrepresented in Educational Data Mining [7]. When compared to this class, the other classes had low ABROCA values (see Table 3), perhaps unsurprising given the similarity of the curves in Figure 2. In general, the ABROCA values were all low with only small differences between classes, leading us to conclude that our model was providing fair predictions across our sociodemographic groups.

Table 3. Slicing analysis by latent class from model trained on all data

LCA Class	AUROC	ABROCA
1 (Black, mid-SES)	0.675	0.011
2 (White/diverse, high SES)	0.696	0.005
3 (White, high SES)	0.706	-
4 (Asian, high SES)	0.691	0.016
5 (Latino, low SES)	0.668	0.008

6. DISCUSSION

On-time 4-year college graduation is something of a “holy-grail” for students, parents, and educators alike [58]. Although efforts to improve college enrollment have been paying off, graduation rates are still lackluster with troublesome achievement gaps stubbornly persisting. Big data approaches might offer a potential solution to improving college graduation rates by providing new insights into the “ingredients” of success. However, they have their own set of limitations and biases, which need to be addressed before we uncover their full potential. Accordingly, we investigated how

predictive models of 4-year college graduation generalized across sociodemographic subgroups identified through latent class analysis and whether they yielded fair predictions for the different groups of students.

6.1 Main Findings

Whilst much of the previous work has relied on limited datasets and traditional statistical techniques [53, 61, 69], we harness a large and diverse dataset with greater potential for generalizability. Specifically, using data from students' college application, we have been able to predict college graduation with moderate accuracy across demographic subgroups. We also show through slicing analysis that a model trained on all data generalizes across all of the subgroups and outperforms individual models (improvement ranging from 6-10%). Training a model on all of the data also reduced the disparity between the subgroups.

By evaluating the ABROCA metric, we were also able to examine which of our subgroups (if any) the classifier was treating unfairly. An unfair model would perform generate less accurate predictions for a given subgroup compared to the baseline group (White High SES in our case). In general, the differences in ABROCA scores were small, suggesting that our model treats no one class significantly different from another.

Whilst all of our models' predictions were substantially more accurate than a chance, there were still inaccuracies. In many ways, this result is reassuring, as we have only considered data from high school. The error that exists across all of our models confirm that college success does not merely depend on a student's environment, past achievement, and experiences. What students experience and do in college plays a critical role in their success. Simply put, there is no predetermination. This gives us hope that through careful data mining we can soon begin to close the achievement gaps that exist across different sociodemographics.

6.2 Applications

It is perhaps easiest to start with how these models should *not* be used. Specifically, the models should not be used to make college admissions decisions because their accuracy scores are insufficient to drive life-changing decisions for individual students and they do not capture several additional factors of the college years that are important for success (e.g. financial needs, life-altering events, social pressures).

We show that it is possible to build generalizing and fair detectors in this domain. On a larger scale, we hope to use this research to provide actionable advice for educators so that they may better prepare students for college success. Further analysis is needed to derive these personalized recommendations, especially since the current models are correlational and thereby unsuited for causal inference.

There are further applications at the college level. Many U.S. colleges have committed to improving 4-year graduation rates [13]. This has resulted in an increased reliance on educational data mining approaches, especially methods to identify "at-risk" students early on [2]. A common issue however is that early warnings are not early enough [5]. Our models consider college application data, so enable us to pre-identify students who might need additional support before they begin their studies. Of course, the models' assessments should be privately communicated to the student's themselves and perhaps to a trusted counselor so they are empowered to take whatever next step is in their best interests.

6.3 Limitations and Future Work

All studies have limitations and ours is no exception. Each of the latent classes had different graduation rates and varied number of instances (a difference of 15,909 instances between the smallest and the largest groups). We attempted to account for class imbalance via synthetic oversampling. However, further work is required to evaluate how the number of instances influenced our results. Future work will also explore the effect of increasing the amount of data used to train models.

Second, our sample only included students who applied to schools that accepted the Common App, which would introduce selection bias, which we cannot account for in this work. Further study is required to investigate how the results generalize to other colleges in the U.S. and beyond.

In addition to addressing these limitations, there are also several promising avenues for future work. For example, since biased variables seem to be predictive in this domain, we will also look into ways to create fair models without fully ignoring the biased variables, perhaps by deriving unbiased proxies.

Our models utilized a range of features including socioeconomic factors, academic history, cognitive ability, the high school environment, and indicators of extracurricular participation that may reflect non-cognitive characteristics. Previous work using the CommonApp-NSC dataset work has shown that different feature groups [33] achieve different classification accuracies. In future work we intend to explore fairness for different feature groups and incorporate insights into the design of fairer models.

When computing the LCA classes, we did not include gender as a variable. However, gender might be more relevant when it comes to specialized outcomes, such as STEM graduation where there are significant disparities across the genders. Relatedly, we also will explore other outcome metrics such as 6-year graduation and STEM graduation, an area with wide achievement gaps when it comes underrepresented groups [56].

6.4 Concluding Remarks

In conclusion, the age of big data brings with it big opportunity, and big responsibility. Although a predictive modeling approach applied to big data has considerable potential in providing new insights to illuminate persistent challenges, these methods have own weaknesses, particularly when it comes to making biased predictions. Thus, we must also consider how our models are perpetuating pre-existing bias and how this can be prevented. Taking the case of predicting on-time college graduation outcomes, we show that our models both generalize and are fair to various sociodemographics subgroups, a critical step towards using these models more broadly.

ACKNOWLEDGMENTS

We are grateful to the Common App for providing us with the dataset, which made this work possible. We also thank Parker Goyer for her assistance in coding the NSC data and to Tammer Ibrahim for his help with the computational infrastructure. This research was supported by the Walton Family Foundation, the Mindset Scholars Network, the Bill & Melinda Gates Foundation, the Joyce Foundation, the Overdeck Family Foundation, and the Raikes Foundation. Any opinions, findings and conclusions, or recommendations expressed in this paper are those of the authors and do not necessarily reflect the views of the funding agencies.

ABSTRACT

Thermal comfort (TC) – how comfortable or satisfied a person is with the temperature of her/his surroundings – is one of the key factors influencing the *indoor environmental quality* of schools, libraries, and offices. We conducted an experiment to explore how TC can impact students' learning. University students ($n = 25$) were randomly assigned to different temperature conditions in an office environment ($25^{\circ}\text{C} \rightarrow 30^{\circ}\text{C}$, or $30^{\circ}\text{C} \rightarrow 25^{\circ}\text{C}$) that were implemented using a combination of heaters and air conditioners over a 1.25 hour session. The task of the participants was to learn from tutorial videos on three different topics, and a test was given after each tutorial. The results suggest that (1) changing the room temperature by a few degrees Celsius can stat. sig. impact students' self-reported TC; (2) the relationship between TC and learning exhibited an inverted U-curve, i.e., should be neither too uncomfortable nor too comfortable. We also explored different computer vision and sensor-based approaches to measure students' thermal comfort automatically. We found that (3) TC can be predicted automatically either from the room temperature or from an infra-red (IR) camera of the face; however, (4) TC prediction from a normal (visible-light) web camera is highly challenging, and only limited predictive power was found in the facial expression features to predict thermal comfort.

Keywords

thermal comfort, automated face analysis

1. INTRODUCTION

Most of the time that people learn takes place indoors. Primary and secondary school students are typically in school buildings for most of the day and do homework in their houses and apartments in the evenings. Adult learners may learn as part of their job in an office or pursue lifelong-learning opportunities at home. The *indoor environment*

quality (IEQ) of where people learn, study, and work can have a significant impact on their physical well-being as well as their cognitive performance [1, 2].

The impact of IEQ on *learning* in particular has a special importance and has begun to interest architects, civil engineers, and educational psychologists in recent years [13]: Young learners in particular might be more sensitive to the influence of the environment due to their age or other physiological characteristics than adults. Students spend many hours each day in schools; however, since students typically have little control over their schools' physical environment, learners may feel great concern about their thermal comfort [8]. Thermal comfort (TC), which is a key component of IEQ, has been defined as "that condition of mind that expresses satisfaction with the thermal environment and is assessed by subjective evaluation" [3]. Prior work (see section below) has shown that suboptimal thermal comfort conditions can negatively affect students' learning. However, to our knowledge, no study to-date has explored the relationship between the impact of TC on learning and *time*. Is it possible that the effect of suboptimal TC could be mild during brief periods of learning but become more severe as the learning session continues? This is one of the questions we explore in this paper.

Measuring thermal comfort: Different people can experience the same temperature and environment differently, and just because one person has a high degree of thermal comfort does not mean her/his friend or peer will. Since thermal comfort is about a person's *satisfaction* with the thermal comfort, it depends not only on the environment itself, but also on the person's physiological and psychological *adaptability* [9, 7] to her/his environment. How adaptive a person is depends, in turn, on how and where a person grew up, e.g., her/his country of origin and its associated climate.

Due to the partially subjective nature of TC, most studies that sought to measure TC used questionnaires [12, 11, 9, 7]. While these are useful, they suffer from drawbacks such as (1) lack of temporal specificity, (2) recency/primacy effects, (3) disruption to regular activities. These can all lead to inaccurate measurements. Therefore, many researchers have explored alternative approaches based on various sensors (e.g., skin-based temperature sensors, cameras) to measure TC automatically [34, 23, 25, 22, 15, 17].

Han Jiang, Matthew Iandoli, Steven Van Dessel, Shichao Liu and Jacob Whitehill "Measuring students' thermal comfort and its impact on learning" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 89 - 98

Automatic facial expression recognition: One of the new forms of human observation that has been enabled by advances in machine learning and computer vision is based on automatic facial expression recognition. With technology, it is possible to automatically detect pain in the human body [18], student engagement [36], driver fatigue [33], and many other affective and cognitive states. Inspired by these studies, we explore in this paper whether automatic analysis of facial expression can help to detect a person’s degree of thermal comfort.

Contributions: In our study, we (1) conduct a randomized experiment to explore the relationship between thermal comfort, the time-on-task, and learning. We also (2) explore different sensors and algorithmic approaches to estimating a person’s thermal comfort automatically.

2. RELATED WORK

During the past 10 years there has been substantial interest (see [13, 26] for literature surveys) in measuring the impact of the IEQ on students’ learning. In Table 1 we categorize the prior work on this subject in terms of IEQ factor (light, air, etc.) as well as the method of measuring learning (subjective impression (SI), test (T) performance, school scores (SS), and randomized experiment (RE)). In addition to studies specifically about thermal comfort (TC) [38], other factors of the IEQ such as lighting, air quality, and noise have been considered. Within this research domain, an important dimension of variability is how learning was measured – by asking participants their subjective impressions, from their school scores, or from a test conducted within the experiment itself. Another dimension of variability is whether the study was observational (i.e., compute a correlation between historical data of the IEQ and historical data of learning) or experimental (i.e., randomly assign participants to conditions). The latter is a generally considered to be the more powerful approach since it avoids many potential confounds (e.g., student engagement) and is the approach we pursue in our study.

2.1 Impact of TC on learning

[20, 8] used subjective impression as the learning performance. They both analyzed the relationships between the IEQ (light, air quality, thermal comfort and noise) and learning. [20] found that the learning performance was negatively correlated with the number of student complaints about IEQ. [8] also explored the students’ satisfaction with IEQ, as well as the TC in particular, from survey data gathered from 631 university students. The results showed that satisfaction of IEQ of the classroom was related to the perceived effect of IEQ on learning. [27] conducted a 1-month test during May-June 2012 at a university in Romania. 18 students’ test results of concentrated attention tests (Kraepelin test) and distributive attention test (Prague test)[31, 30] were recorded. The conductors used room temperature, relative humidity and CO₂ concentration to predict test scores. Their results suggested that these indoor environment factors could strongly impact students’ learning performance. [35] conducted an experiment to explore the impact of air temperature on students’ performance. The results indicated that with the same accuracy, students would increase their speed when performing the language-based and numerical performance tasks if the room temperature was re-

duced from 25°C to 20°C in late summer. [24] randomly assigned the participants into different conditions to perform a computer-based reading and learning task. They found that TC had a low and non-significant relationship with the performance; the participants in the extreme condition believed that the temperature had a larger negative impact on their performance than the participants in a normal condition. In [16], the researchers conducted an experiment to explore the impact of TC in 1-on-1 cognitive tasks when students are with a tutor. All the participants experienced all temperature conditions (10°C, 14°C, 15°C, 16°C, 18°C, 20°C). Their experiment indicated that there was an inverted-U relationship between thermal sensation and pupils’ learning performance. A seven point scale of thermal sensation, according to [3], was used. The meaning of the number from -3 to 3 was “cold”, “cool”, “slightly cool”, “neutral”, “slightly warm”, “warm” and “hot” successfully. The results showed that students’ performance was better in the cool or slightly cool conditions compared to the hot condition.

2.2 Measuring thermal comfort

How to measure thermal comfort has been explored for many years. While questionnaires from each person about her/his own TC is useful, they can be inconvenient and tedious. Researchers have thus sought to devise alternative measures that can be measured automatically from various sensors.

Environmental sensors: For instance, the PMV-PPD model, proposed by [12, 11], uses air temperature, mean radiant temperature, air velocity, humidity, and human variables to calculate the Predicted Mean Vote (PMV) of a group of people’s averaged thermal sensation according to [3]. The Predicted Percentage of Dissatisfied (PPD) utilizes PMV to calculate the percentage of people who might complain about their thermal environment.

Body sensors: [34] used skin temperature sensors to collect upper extremity (finger, hand, forearm) skin temperatures and explored how these temperatures related to thermal sensation. [23] explored different configurations of where to place the temperature sensors on the body and identified particular configurations that were most effective.

Cameras: More recently, with the development of machine vision, researchers also explored predicting thermal comfort through cameras. [25] showed that the averaged forehead temperature from infrared (IR) images was correlated with people’s thermal sensation and thermal comfort. [15, 17] leveraged the human thermoregulation process and then applied Eulerian Video Magnification algorithm[37] to filter the visible-light RGB images to predict thermoregulation states, which is one indicator of thermal comfort.

3. EXPERIMENT

In order to assess the impact of thermal comfort on learning and how this effect could change over time, we conducted a laboratory-based learning experiment (approved by WPI’s IRB #18-0372) in which university students ($n = 25$) watched three lecture videos, answered surveys on their thermal comfort, and completed a quiz on what they learned. During the experiment, the indoor environment conditions were monitored and controlled according to a schedule defined by each participant’s randomly assigned experimental

condition. We also deployed a variety of sensors – camera, environmental, and body – to measure the temperature of the environment and of each participant. These sensor measurements, along with participants’ survey responses, allow us also to explore different automated approaches to estimating a person’s thermal comfort.

3.1 Recruitment of participants

We recruited participants for the experiment through an email list at our university. In the end, 25 students (of whom 9 were female) participated in our experiment. All of them were either undergraduate or graduate students. Each participant was paid for \$20 gift card for his/her participation.

3.2 Procedure

This experiment was conducted on each participant individually and was divided into four sessions. Each session was 21 minutes. Therefore, every participant would sit at a desk around 84 minutes in total. In the first session (adaptation session), each participant gave informed consent, placed the skin-based temperature sensors on her/his body, and listened to the experimenter’s instructions. The purpose of the adaptation session was to neutralize the potential impact of the outside weather conditions or physical activity (e.g., running to class) before the experiment. In each of the remaining three sessions, the participant watched a tutorial video (10 minutes), answered a quiz about it (<5 minutes), completed a thermal comfort survey (<5 minutes), and then took a break. The length of the break (21 min – VideoLength – QuizTime – SurveyTime) depended on how long the participant took to complete the quiz and survey. The order of the tutorial videos was randomized, as was the order of the temperature conditions (warm to neutral, or neutral to warm); see Conditions subsection below. Sensor measurements, including video of the face, were recorded throughout all three tutorial sessions.

After the participant finished putting on the body sensors, the experimenter started the videorecording from the laptop-based web camera, typed the participant’s ID into the webpage, turned the time controller on, and then asked the participant to press the “Start” button whenever she/he was ready. The experimenter then left the room and stayed in the room next-door throughout the rest of the experiment. Using remote access software, the experimenter took an IR image of the participant at the beginning of each tu-

Figure 1: Experimental setup of the desk, laptop, and cameras.

Figure 2: Tutorial session procedure

torial video during the tutorial sessions. See Figure 2 for a schematic of the procedure.

3.3 Environmental controls

We used 4 heaters (to increase the room temperature) and 1 air conditioner (to decrease temperature). In order to maintain the temperature at a constant level, we also deployed 3 thermal controllers. Moreover, in order to change the room temperature (from either warm to neutral, or neutral to warm), we also used 4 timers. To maintain the room temperature to be at least 25°C, 1 heater was always turned on. 3 thermal controllers and 3 timers were connected to the other heaters. The thermal controllers were used to keep the room temperature around 30°C. Timers were used to control when the heaters and air conditioners were turned on and off. The heaters and air conditioner were oriented so that the air did not blow directly onto the participant.

3.4 Sensors

All sensors were adjusted carefully before we started our experiment. They are listed as follows:

Figure 3: Positions of skin-based temperature sensors on the body.

1. 4 skin temperature sensors. We followed the positions in [23] (see Figure 3). These sensors were used to measure the participant's body temperatures at four different body locations and record the temperature every 1 minute. Sensors were attached using medical tape.
2. Room temperature sensors. These sensors were used to measure the room air temperature at different heights (0.1m, 0.6m, 1.1m and 1.7m) and recorded every 1 minute.
3. 1 web camera on the laptop pointed at the participant's face. Note that the video was lost for 1 out of 25 participants; hence, for our experiments on using the web camera to predict thermal comfort, $n = 24$.
4. 1 infrared (IR) camera pointed at the participant's face. The camera recorded only images, not video. Using the camera's temperature calibration software, the IR images can be used to estimate the participant's face temperature directly.

3.5 Materials

Tutorial videos: We used three 10 min-long tutorial videos and quizzes that were used in a prior study by [32]. The order in which the tutorial videos were presented to each participant was randomized; this was necessary to remove the potential confound that the subject matter, rather than the thermal comfort or time during the learning session, influenced the learning gains. All videos were about social, philosophical, and ethical issues: (1) honesty, (2) language and thought, and (3) empathy.

Thermal comfort survey: We used the same thermal comfort questionnaire survey as in [22, 21]. The survey asks questions such as, "Rate your whole body thermal sensation", "Rate your thermal body comfort", "How sleep/alert do you feel?", and "How easy/difficult is it to concentrate?" The scale was from -3 to +3 with a resolution of 0.1.

Figure 4: Top: Experiment lab Photo; Bottom Left: Top view of Lab and sensors' position. The participant was facing the direction with the arrow; Bottom Right: Room temperature sensors in different heights

3.6 Conditions

Each participant was randomly assigned to one of two temperature conditions: neutral to warm (25°C to 30°C), and warm to neutral (30°C to 25°C). By randomizing the thermal conditions, we avoid the potential confound that students' performance changed in different sessions not due to thermal comfort but due to other factors related to time, e.g., fatigue. If the participant was in the neutral to warm condition, the room temperature in the adaptation session was maintained at 25°C until the end of the first tutorial session; it was then increased to 30°C in the second tutorial session and was maintained at this level until the end of the third tutorial session. See Figure 5.

3.7 Data collection

Using the sensors, we collected several kinds of data from each person: (1) Video from the web-camera (at 30 fps); (2) Infrared images (1 every 21 minutes); (3) room temperature, CO₂, and relative humidity (1 measurement every minute); (4) body temperature (1 every minute for each sensor); (5) each participant's start/end times of each tutorial video, quiz, and survey; (6) each participant's quiz scores.

Figure 5: The change of room temperature in different conditions

Figure 6: Histogram of thermal comfort in our experiment

4. ANALYSIS

Our analysis was focused on two questions: (1) what is the relationship between thermal comfort, temperature, and learning? (2) How can we use the various sensors to estimate participants' self-reported thermal comfort automatically?

4.1 Impact of room temperature on thermal comfort

In our experiment, the range of the room temperature was from 25°C to 30°C. This was not a huge change in the temperature. One of our goals was to assess whether this magnitude of temperature change could influence body thermal comfort. As defined in the thermal comfort survey that we used [3], the range of thermal comfort was from -3 to 3, where -3 means "very uncomfortable" and 3 means "very comfortable". Based on the histogram of body thermal comfort in our experiment in Figure 6, we see that the participants rarely (10 total votes) considered their thermal comfort to be highly uncomfortable (a rating of -3, -2). This indicated that our setting of the experiment was relatively comfortable for most of the participants. Did the modest temperature changes induced during the experiment impact participants' thermal comfort? To investigate, we considered models including either linear or quadratic terms for room temperature (computed as the average of the temperature sensors at different heights). The quadratic model did not give a stat. sig. better model fit, and hence we used a linear model; see Figure 7. The Pearson correlation between the model's predictions and self-reported thermal comfort scores was $r = -0.436$, $p < 0.001$, i.e., within the temperature range of our experiment, higher temperature resulted

Figure 7: Thermal comfort VS Avg room temperature

in lower thermal comfort. Based on the estimated regression coefficient, increasing the room temperature by one degree in our temperature range results in a reduction of thermal comfort by 0.32. Note that we also tried modeling thermal comfort and temperature (linearly) with a participant-specific offset as a random effect and obtained similar results.

4.2 Relationship between thermal comfort, learning, and time

After showing the change of room temperature in our experiment could influence the participants' thermal comfort, we assessed whether thermal comfort was related to participants' performance in the learning task. A scatter-plot of the quiz scores versus self-reported thermal comfort scores is shown in Figure 8. Neither the Pearson nor the Spearman correlations between quiz score and thermal comfort were significant. However, after visually examining the scatter-plot, we noticed a slight "inverted U" shape; this has also been noted in prior work [29, 28]. This shape indicates that when the participants felt too comfortable or too uncomfortable, their quiz score were lower; when the thermal comfort state was in the middle, their quiz score was higher. We found some support for this hypothesis in our data: the Spearman correlation between the *square* of self-reported thermal comfort and quiz score was negative ($r = -0.235$) and statistically significant ($p = 0.0042$). The quadratic model of self-reported thermal comfort gives a stat. sig. better fit than the linear model (likelihood ratio test, $p = 0.002$).

To explore this more rigorously by accounting for repeated measures, we also used a mixed-effect model with a random effect to model an offset for each unique participant. Due to different tutorial videos having different difficulties, we also considered the video_id as the random effect. We studied the relationship between thermal comfort and quiz score within each of the three tutorial session (1, 2, 3) separately. To our surprise, in the first two tutorial session, the impact of the square of the body thermal comfort (i.e., TC^2) was not significant ($p > 0.05$). However, in the last (third) session, the impact was negative and stat. sig. ($p = 0.013$). The estimated magnitude was that a change in 1 level of thermal comfort decreases the quiz score by 0.2 points (the maximum score was 6 points). A possible interpretation is

Figure 8: Thermal comfort VS Quiz score

Table 2: Effect size (Cohen’s f^2) of TC^2 in each tutorial session

Session No.	Effect size
1	0.007
2	0.044
3	0.308

that, as time went on, the participants might feel more tired or bored. At first, they could force themselves to focus on the tutorial videos and answer questions. However, when they became fatigued or bored, an uncomfortable thermal comfort might start to show its influence. See Table 2 for the effect size (calculated based on the marginal R^2) in each tutorial session.

4.3 Relationship between thermal comfort and sleepiness

The survey that each participant completed after every tutorial session contained questions not just about thermal comfort, but also about how sleepy they felt. The values ranged from -3 (very sleepy) to +3 (very alert). The correlation between thermal comfort and sleepiness was positive (0.32) and stat. sig. ($p = 0.0084$).

4.4 Relationship between engagement and learning

To explore whether the perceived level of student engagement, as judged by an external observer, was related to students’ learning, we manually labeled video frames from each participant’s face video. We extracted 1 frame every 20 seconds for each of the 3 tutorial sessions of all the participants. These pictures were labeled for the appearance of ‘engagement’ following the definitions in [36]. Level 1 is “not engaged”, level 2 is “nominally engaged”, level 3 is “engaged”, and level 4 is “very engaged”; see Figure 9 for a representative image of each label. During labeling, the images were randomized over time and also over participants; hence, the engagement scores were unbiased w.r.t. participants’ self-reported thermal comfort. We averaged the engagement for each participant per each of the three tutorial sessions, and then used a mixed effect model to analyze the relationship between quiz score and engagement. The participant_id was still the random effect. Since we had a prior hypothesis

Figure 9: Participants in different engagement levels.

Figure 10: Manually cropped face for infrared images. Top: face when thermal comfort is -0.6. Bottom: face when thermal comfort is 2.7.

that engagement was positively correlated with learning, we used a 1-tailed t-test. The result showed that this positive correlation was significant ($p = 0.032$).

5. AUTOMATIC DETECTION OF THERMAL COMFORT

The primary method of estimating thermal comfort is via self-report on a survey. Might there be an automated way of obtaining this information that is less intrusive and gives higher temporal resolution? This could be useful to advance research on the IEQ and learning. Moreover, it could also set the stage for smart learning environments in which localized ventilation, heating, and cooling systems can optimize the thermal comfort for each learner. With these goals in mind, we explored several approaches to automatically estimating thermal comfort using the different sensors we deployed in our experiment.

5.1 Infrared camera

Per participant, 3 IR images were collected (one per tutorial session). From each IR image, we manually cropped the face for infrared images from IR camera and calculated the average face temperature for each tutorial session. For each IR image, we cropped the face between two ears for width, and from forehead to chin for length; see Figure 10. We then calculated the mean temperature within the face region and used it to predict thermal comfort. Using a mixed-effect model (with participant_id as a random effect), we found that the correlation between the face temperature, as computed from the calibrated IR image, and thermal comfort

Table 3: Skin Temp. VS Thermal comfort

Sensor	Pearson Correlation	p-value
D	-0.273	0.018
K	-0.174	0.136
O	-0.186	0.11
Q	-0.28	0.015

was -0.34 ($p = 0.0029$). In other words, a hotter face was associated with lower thermal comfort.

5.2 Skin sensors of body temperature

We averaged the skin temperature from 4 skin sensors for each tutorial session. The correlations between thermal comfort and averaged skin temperature are shown in Table 3.

With statistical significance, the correlations of the skin temperature at position D and Q indicated that they had a negative correlation with body thermal comfort. These two correlations also remained significant when we applied the mixed-effect model and set participant_id as random effect.

5.3 Web camera

Even though the results of skin sensors and infrared cameras showed that we could use them to detect thermal comfort, we were still interested in whether an ordinary (visible light) web camera can be used to detect thermal comfort. In contrast to skin sensors, web cameras are less intrusive – they require no skin contact or medical tape. In contrast to IR cameras, they are less expensive and more widely available.

While one could consider a “black box” approach such as a CNN-LSTM in which all the pixels of an entire video segment is used to predict thermal comfort, the relatively small size of our dataset ($n = 24$) makes this approach difficult. Instead, we investigated whether the much lower-dimensional feature representation of facial expressions can reveal a person’s thermal comfort. For example, we reported above that sleepiness is associated with thermal comfort, and this might be revealed in a person’s facial expression; this approach was used in [33] to detect drowsiness when driving a car.

After watching the videos, our subjective impression was that predicting thermal comfort from the face was very difficult. In the temperature range of our experiment setting, the facial expressions in different temperature condition did not vary greatly. Nevertheless, we tried three approaches: (1) estimate thermal comfort directly from the average facial features values extracted from OpenFace [4] over the time series of face images; (2) estimate thermal comfort from a Gabor-filtered time series of facial features; and (3) train a recurrent neural network to analyze the raw time series.

5.3.1 Individual face movements

From each frame in each 10-minute video sequence just prior to the self-reported thermal comfort survey of each tutorial session of each participant, we used OpenFace to extract the facial action units (AUs 1, 2, 4, 5, 6, 7, 9, 10, 12, 14, 15, 17, 20, 23, 25, 26, 45). In addition, we also calculated the size of the face – this could be useful for determining

**Figure 11: Landmarks from OpenFace**

if the participant leaned toward or away from the camera. Next, we extracted the head pose. Finally, we computed the distance between the eye-lids – this could give some measure of drowsiness.

For the left eye, we first calculated the central point of landmark 37 and 38, the central point of landmark 41 and 40, and then, calculated the distance between these two central points. For the right eye, we calculated the distance used landmark 43, 44, 47 and 46 as the same approach as the left eye. The eye-lid distance was the mean of the left distance and the right distance. We also estimated the size of the face box as an indication of whether a person was leaning towards or away from the camera: we first calculated the central of landmark 19 and 24, and then calculated the distance between the central and landmark 8, and also the distance between the landmark 0 and 16. The final face size was the product of the two distance. See Figure 11.

Using the above feature set, we examined the Pearson correlation between each mean feature value (averaged over each 10-minute time series) and self-reported thermal comfort. Only two features were stat. sig. correlated: AU 6 (Pearson $r = 0.244$, $p = 0.038$; see Figure 12) – cheek raiser – and the eye-lid distance, calculated by the landmarks on the eyes, was also correlated to thermal comfort with significant (Spearman $r = -0.27$, $p = 0.02$). The latter correlation suggests that smaller eye opening is associated with larger thermal comfort; this is consistent with the notion that thermal comfort that is “too high” may cause people to become sleepy.

5.3.2 Gabor filtered time series

A 1-D (temporal) Gabor filter is a complex-valued band-pass filter, with a specifiable center frequency and bandwidth, whose impulse response is local in both time and frequency; an example of the real component of one filter is shown in Figure 13. Gabor filters have been applied to var-

Figure 12: Example of AU 6 (<https://www.cs.cmu.edu/~face/facs.htm>)

Figure 13: One example of real gabor filter. Frequency: 3.0; bandwidth: 0.9492

ious facial expression recognition tasks [33] and can capture certain patterns of a raw time series. For instance, they can capture wave-like patterns such as repeated blinking or eye closure. Here, we explored whether they could be helpful for predicting thermal comfort.

We applied Gabor filter to the AUs, face size, head pose, and eye-lid distance features. The frequency was selected from {8.0, 7.0, 6.0, 5.0, 4.0, 3.0, 2.25, 1.6875, 1.2656, 0.9492, 0.7119, 0.5339, 0.4005, 0.3003, 0.2253, 0.1689, 0.01, 0.} and the bandwidth was selected from the same set without 0. Thus, 918 filters (the combination of 18 frequencies, 17 bandwidths and real, imaginary and energy Gabor filters) were applied to each AU and head features, which was the same filter bank as [33]. We used forward feature selection to pick the top 5 filtered features and then used linear regression on these top 5 features to predict thermal comfort. However, even the best Pearson correlation was very low ($r = 0.02$), suggesting that this approach had limited predictive power.

5.3.3 Recurrent neural networks

Recurrent neural networks such as LSTM and GRU, are powerful models for dealing with time series. We explored whether a GRU (Gated Recurrent Unit) network can analyze the facial expression series to estimate thermal comfort. We trained a GRU model from the features extracted using OpenFace described above using leave-one-person-out cross-validation to measure accuracy of the approach. Hyper-parameters were selected from the sets {learning rate: {0.0001, 0.0005, 0.001}, hidden units: {8, 16, 32}, epoch: 50, optimizer: {Adam, SGD}. For each fold, we randomly selected 5 participants as the validation set (for hyperparameter validation), and the remaining 18 participants as the training set. Training every 5 epochs, the model would be applied to validation set and test set.

After tuning the hyper-parameters on the validation set, the best combination was {learning rate: 0.0005, hidden units: 32, epoch: 15, optimizer: Adam}. The average (over all 24 folds) correlation between predicted and actual thermal comfort scores was 0.248; the result was statistically significant ($p = 0.0425$, Wilcoxon signed-rank test). We note, however, that this result is no larger than the magnitude of the correlation between the eye-lid distance and thermal comfort reported above.

6. DISCUSSION AND CONCLUSION

We conducted an experiment in to investigate the relationship between thermal comfort and students' performance in a computer-based learning task in the classroom. We also explored different sensors and predictive models to measure thermal comfort automatically.

Key results: 1) Changing the room temperature by a few degrees Celsius could stat. sig. impact students' self-reported TC; (2) Our experimental data provide evidence that learning is optimal when thermal comfort is neither too high nor too low (inverted U relationship), corroborating prior work. However, we also found a more nuanced relationship than had been identified in prior literature: the impact of thermal comfort on learning was stronger during the third tutorial session (later in time) compared to the first two sessions. (3) Engagement, as labeled by an external observer, was correlated with learning. (4) Thermal comfort can be predicted from the face temperature using an IR camera. (5) Facial expression, at least in the ways we analyzed it, carries only limited information about thermal comfort.

Future work: Given a larger video dataset of face images and associated self-reported thermal comfort scores, we could explore more powerful prediction models that directly predict thermal comfort from the face pixels. This might offer more powerful information than the facial expression estimates from OpenFace.

ABSTRACT

Demographic information often proves useful for finding subpopulations in educational data. Unfortunately, it is often not collected in the log files of online learning systems, which serve as one of the primary sources of data for the Educational Data Mining community. Recent work has sought to address this issue by investigating school-level differences in demographics, which can be used to discover trends in data where individual-level variation may be difficult or impossible to acquire. In this study, we use this approach to investigate the effect of demographic patterns on hint usage in an elementary level mathematics system, comparing this use to performance and motivational measures. In doing so, we expand upon the research into help-seeking behaviors, which typically takes a cognitive approach. Our results suggest the need to better understand what social factors are most likely to motivate help-seeking behaviors, particularly since research on their effectiveness has been mixed.

Help-seeking, Demographics, Math Learning, Math Identity, Self Concept, Self Regulated Learning

1. INTRODUCTION

Many studies into complex constructs like motivation, interest, and engagement involve either small-scale experiments or larger convenient samples of middle-class, undergraduate students (see discussion in [21]), which can make it difficult to determine the extent to which these findings will generalize to new populations of students. This is often due to the practical constraints of research projects involving the budget, recruitment, accessibility and time required to acquire the level of detail used in these studies. However, this trade-off sometimes means that conclusions are not replicated across broad demographic contexts. Conversely, Educational Data Mining (EDM) researchers often have larger sample sizes than are seen in experimental psychology, for example, but the source of typical EDM data (i.e., intelligent tutoring systems) often limits the practicality of obtaining demographic variables from individual students.

Shamya Karumbaiah, Jaclyn Ocumpaugh and Ryan S Baker "The Influence of School Demographics on the Relationship Between Students' Help-Seeking Behavior and Performance and Motivational Measures" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 99 - 108

Beyond practicality (e.g., the ease of acquiring log-file data on student interactions compared to student demographic data), there are sometimes other legitimate concerns, including those related to student privacy. For example, even when a partner school or university has documented the demographics of individual students, their release to a researcher increases the risk of potentially re-identifying students, particularly in rural parts of the country where the analysis of say, the seven children of a minority ethnic group in a small school narrows the potential matches for sensitive information considerably.

Yet considerable research shows that demographic factors are often related to differences in educational outcomes more generally (see [14]) and to constructs related to motivation more specifically [50, 50, 44]. This suggests that researchers in the EDM community should make greater efforts to overcome the challenges involved in collecting demographic data in order to ensure population validity (e.g., [29]). As such, some researchers within the EDM community have sought to extend student learning models to include information from the broader context, building models at the class, school-, school-cluster level instead of just the student-level [47, 31]. [49] used school-level demographics and students' prior performance to cluster schools into groups, improving model performance.

This study uses this approach to investigate hint-usage, incorporating the broader demographic context into the investigation while also answering a call to pay greater attention to the social factors influencing help seeking behaviors after a recent review of the literature found that their effectiveness was highly variable [15]. We do so in the context of Reasoning Mind—an Intelligent Tutoring System for elementary mathematics—where we explore how readily-available school-level demographics might reveal how hint usage correlates to measures of student performance and motivation (i.e., mathematics self-concept).

2. PRIOR WORK

Help - mostly in the form of on-demand, contextual, real-time hints - is a common feature in most Intelligent Tutoring Systems (ITSs) [46] and has long been believed to foster emerging concepts and principles in a student's learning [7] and support struggling students during problem-solving [1]. Yet help-seeking behaviors are not always beneficial [1, 2, 4]. While much of the prior work on help-seeking in ITSs has focused strictly on its cognitive effects, other research suggests that social factors may influence these patterns.

2.1 Help-Seeking: A Cognitive Lens

The literature on help-seeking behaviors in ITS now stretches back over twenty years (see extensive review in [4]). As it quickly became apparent that the availability of hints did not ensure their effective use, work began to identify the factors that led to a positive relationship between help-seeking behaviors and student learning.

In one of the earliest studies, Anderson et al. [6], compared the use of explanatory hints and so-called bottom-out hints (which simply provided the student with the correct answer and found that neither hint type was correlated with learning. In part, this may have been due to selection bias. That is, hint usage is typically a sign of struggling students, who often do not make substantial learning gains (see discussion in [4]).

After early discoveries of a negative correlation between hint usage on student learning in one context [1], researchers began to develop a taxonomy of maladaptive help-seeking behaviors—including categories like help abuse (the overuse of help) and help avoidance (the underuse of help)—was also developed [13]. Most studies analyzed the effectiveness of hints by focusing on the relationship between help-seeking behavior(s) and student outcome(s), with some researchers emphasizing that the intentionality of help-seeking behavior makes it a good candidate for understanding students' self-regulated learning (SRL) strategies [4, 16].

A number of studies have attempted to identify the degree of help needed at any given moment (e.g., Koedinger & Aleven's [24] *assistance dilemma*), and experimental results have resulted in notable findings. For example, (1) on-demand hints led to greater learning gains than automatic hints in middle-school mathematics [32]; (2) hint content (goal feedback versus other kinds of feedback) is related to student learning in Geometry [27]; (3) hints about which step to try next to improve student learning in logic proof [36].

In general, the review of the literature suggests that increasing hint usage does not always lead to better domain-level learning [4]. However, the EDM literature on help-seeking in ITSs has produced research which aggregates into a complicated and contradictory narrative, including: (1) a negative association between hint usage and learning [2]; (2) a positive association between hint usage and learning [11, 48]; (3) a positive association between hint usage and learning only when time per hint level is considered [25] or when adaptive versus maladaptive help-seeking is differentiated [3]; (4) a positive association between time spent in bottom-out hints and learning [35]; (5) a negative association between the number of bottom-out hints used and learning [26]; (6) positive benefits for students but only when they have a medium level of skill [33]; (7) a negative association between help avoidance and learning early within practice [5] and on a transfer post-test [9].

In addition, individual differences in self-regulation were observed in how students process hints and how that impacts their performance [16]. Vaessen et al [45] found that students' achievement goals (mastery and performance goals) are closely related with their help-seeking and could be used to predict their strategies for help-seeking. Despite a considerable volume of research, the effectiveness of help-seeking remains an open question—and the clearest thing that we can say is that the relationship between hint usage and learning is complicated.

2.2 Help-Seeking: A Social Lens

While the role of social factors on help-seeking behaviors has not been the primary focus of the EDM community (see [4]), the social evaluation of help-seeking behaviors is well established in the literature. For instance, some learners may feel that asking for help is either a sign of incompetence or a challenge to their autonomy [39]. Likewise, Howley et al. [18] suggests that asking for help may trigger experiences of evaluation anxiety – the fear of being judged.

These kinds of concerns seem ripe for socio-cultural variation, and a few studies have begun to explore how these differences may emerge. For example, Tai et al. [38] increased students' help-seeking behaviors by changing the way they labeled those actions within the system. That is, they started by referring to the ITS as the students' teammate, and the designed the system so that students who needed help could choose to "work together" with the system. This adaption apparently reduced the ego-threat related to admitting a lack of knowledge (e.g., [39]) and improved student learning.

Other studies have specifically investigated demographic differences in help-seeking behaviors. Ogan et al. [30] found that the EDM models on effective help-seeking did not transfer well between countries (namely Costa Rica, the Philippines, and the USA). Likewise, Arroyo et al. [8] found that the effectiveness of different hint designs varied by gender. Specifically, girls benefited more from highly interactive hints, while boys did better with less interactive hints.

Thus, there is a need for more research to look at social factors while studying help-seeking. Such studies should focus on students' broader context to understand under what circumstances lead to desired student outcome. In this paper, we study students' help-seeking behavior in an online math tutor used in traditional classrooms during regular instruction. Given the context in which the students use this ITS, we focus on school as the social context and analyze the influence of school demographics on the relationship between student outcomes (math performance and math self-concept) and their help-seeking behavior. We aim to shift the focus of help-seeking research in the EDM community from purely cognitive factors to the contextual factors that might play a more prominent role than is assumed.

2.3 The Role of Demographics in Predicting Student Outcomes

This section summarizes prior work on the role of demographics in the student outcomes of interest in this study - math performance and math self concept.

2.3.1 Demographics and Math Performance

The literature addressing demographic differences in learning outcomes (at least in a U.S. context) is now so vast that it would be difficult to review even if it were limited to a single domain (e.g., mathematics). Once referred to as the achievement gap, more and more scholars are now discussing it in terms of an opportunity gap, as findings generally show that achievement patterns favor groups for whom the educational system was initially designed.

Scholars point out that reframing this discussion in terms of opportunities to learn emphasizes the need to address the environmental inadequacies that may occur. Childs [14] analysis shows, for example, that minority students are just as likely to value mathematics, but are less likely to attend schools where advanced mathematics classes are offered.

However, less tangible differences may also play a role. For example, if students' patterns of communication are different than those expected by educators (e.g., [19]), their attempts at help-seeking may not receive adequate uptake. Such experiences could discourage students from future help-seeking behaviors, although one could imagine that the ability to get help from an ITS could also mitigate this reluctance.

2.3.2 Demographics and Self-Concept

Demographic variables have also been shown to correlate with motivational constructs, like math self-concept. Math self-concept (sometimes used interchangeably with self-efficacy, although see [12]) has been found to be a predictor of various measures of achievement and career choice (see [13]). It has also been linked to motivational constructs, including achievement goal orientation, anxiety, and self-concept [34].

Early work proposed that self-efficacy was a product of a person's own accomplishments and the feedback they receive on their work [10, 43]; however, more recent studies have indicated that the source of self-efficacy may vary along demographic lines like gender and ethnicity [50, 50, 44]. For example, Klassen [23] investigation of self-efficacy among seventh grade students found that ethnic majority students followed Bandura's predictions, citing personal achievements as a source of self-efficacy, but ethnic minority students were more likely to cite social factors. Else-Quest, et al. [15] studied the intersection of gender, ethnicity, and achievement in 10th grade students from a large northeastern city and found that males reported greater math self-concept and expectation of success as compared females, but no gender differences across ethnic groups were found.

Other research on self-efficacy suggests that it is malleable and can be influenced by social agents [51], and there are significant efforts to understand how to support underrepresented groups, who may struggle against implicit stereotypes on top of normal learning struggles as their domain knowledge matures [37]. Previous research shows that scores on social identity ratings (e.g. gender and cultural identity ratings) peak when people are experiencing uncertainty [17]. This could suggest that students could become more susceptible to negative cultural stereotypes (e.g., [37]), particularly those related to STEM performance, during periods of confusion associated with learning, making help-seeking an important behavior to study for its associations with self-concept.

Given these findings, it seems likely that self-concept could vary not just by the demographics of individual students, but also based on how those demographics influence the cultural interactions at a school level. That is, in a school where larger numbers of students share a particular demographic characteristic, we might see help-seeking behaviors that emerge as a reflection of the practices more typical of that group.

3. DATA COLLECTION

3.1 Reasoning Mind

This study analyzes data from students using Reasoning Mind (RM) Foundations (Figure 1), an intelligent tutoring system for elementary mathematics, produced by Imagine Learning. It currently serves over 100,000 U.S. students annually. The majority of these students are in Texas, but they represent a range of traditionally underrepresented populations across rural, urban, and suburban schools. Key components of this system include socio-technical innovations, including those that are designed to

directly support teachers [21] and those that are designed to mimic other social experiences in the classroom, including both virtual peers and the signature pedagogical agent, known as the Genie, that guides students in their learning.

Figure 1. Reasoning Mind Foundations home screen (left) and an example problem (right)

In this blended environment, students learn through self-paced problem solving, interactive explanations, and skill-based games. Problem sets are classified into three groups based on increasing levels of difficulty: (1) A-level problems on fundamental skills; (2) B-level (optional) problems on a combination of skills; and (3) C-level (optional) problems on higher-order thinking skills. Our past study [20] suggests a close relationship between inconsistencies in students' math performance and their math self-concept – the two student outcomes studied in this paper. Reasoning Mind Foundations is generally used in traditional classrooms. Teachers assign/unlock problem sets for students based on the topic of instruction. Past studies of Reasoning Mind Foundations have shown high student and teacher acceptance, increases in test scores, high time on task, and a positive affective profile [21].

3.2 Hints in Reasoning Mind

Hints are an integral part of Reasoning Mind Foundations. These are delivered only on student request and contains conceptual feedback intended to help students solve the problem. Figure 2 demonstrates a hint in the system for one of the basic A-level problem in Reasoning Mind Foundations. They are multi-level and do not always contain a bottom-out hint.

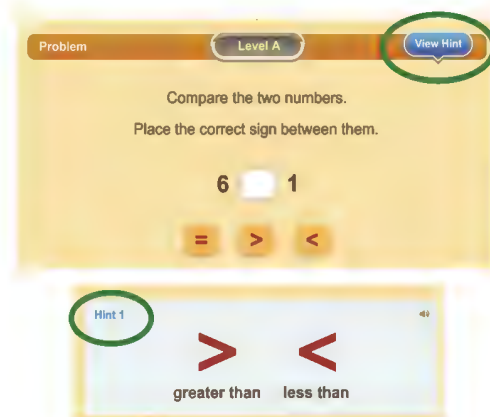

Figure 2. Top - Problem screen with a button to view hint (highlighted in green) Bottom - Hint displayed to the student when they request to view

3.3 Participant Schools

In order to ensure consistency in the type of data used to characterize schools, this study limits itself to Reasoning Mind

schools that fall under the purview of the Texas Education Agency's (TEA) and further filters out schools where less than 25 students were using the software to avoid noise in the correlations reported below. This resulted in data from 110 Texas schools across 25 school districts who used Reasoning Mind during the academic year 2017-2018 as part of their regular mathematics instruction. There are a total of 9,122 2nd through 5th grade students in this data (4,749 2nd graders, 1,964 3rd graders, 1,582 4th graders, and 827 5th graders). On average, there were 75 students using Reasoning Mind Foundations per school (min = 25; SD = 70) and 364 per school district (SD = 730), with one large urban district in Texas constituting the majority of our data, with 3,039 students across 62 schools.

Comprehensive log data captured student interactions with the system for the entire period, resulting in data for all 9,122 students. Surveys were administered once at the beginning and once at the end of the year to collect data on student math identity, resulting in complete surveys for 2,238 students.

4. DATA EXPLORATION

Considerable variation exists in the measures being analyzed in this study: help-seeking behaviors (i.e., hint usage), math performance, and pre- and post-year measures of math self concept.

4.1 Exploring Help-Seeking

From the interaction log data, we operationalize help-seeking behavior using as the number of hints used by a student in Reasoning Mind Foundations. As shown in Figure 3 (left), students in this study averaged less than 30 hint requests annually (mean = 27.01, SD = 55.72).

4.2 Exploring Math Performance

For the purposes of this paper, math performance is defined as the accuracy of student responses to A-level problems in Reasoning Mind Foundations. Accuracy on these problems, which represent the core curriculum within the software, is computed from the interaction log data. As presented in Figure 3 (right), student-level calculations show a mean of 0.77 (SD = 0.14).

Figure 3. Distribution of the number of hints (left) and math performance (accuracy in A-level problems; right). The green line in the box indicates the median value.

4.3 Exploring Math Self Concept

Students' self concept in mathematics was measured using a five-item survey adapted from Marsh et al. [28]. This survey was

administered twice--once at the beginning of the academic year (pre) and once at the end of the academic year (post). The survey included questions like *Math just isn't my thing; Some topics in math are just so hard that I know from the start I'll never understand them*. Students took the survey voluntarily, and each item in the survey was answered with a four-point Likert scale.

This study analyzes survey responses from 2,238 students across 22 Texas schools. The distribution of students' responses is given in Figure 4 (self concept pre: mean = 2.64 standard deviation = 0.77; self concept post: mean = 2.44, standard deviation = 0.80). The internal consistency of these items was found to be satisfactory with a Cronbach's α of 0.74.

Figure 4. Distribution of number of pre and post measures of math self concept.

4.4 Exploring School-Level Differences

Next, we explored the school-level differences in student outcomes (math performance and self concept) and hint usage. As we can see in Figure 5 and Table 1, there is considerable variance in the variable aggregates (mean) across the schools, especially in hint usage and math performance.

Table 1. Mean and standard deviation (SD) of the school-level aggregates of the variable and outcomes

	Mean	SD
Hint Usage	24.5	21.3
Math Performance	0.78	0.04
Math Self Concept (Pre)	2.69	0.35
Math Self Concept (Post)	2.43	0.15

Figure 5. Distribution of school-level aggregates of the variable and outcomes.

4.5 Summarizing School-Level Demographics

We characterize the schools in our sample using demographics from the Texas Education Agency's (TEA) public data repository. These data capture the contextual factors that are likely to affect the school culture or climate and defines the social context in which students using RM Foundations.

Table 2. Mean and standard deviation (SD) of the school-level demographics. EcD - Economically Disadvantaged; LEP - Limited English Proficiency; SpEd - Special Education

	Mean	SD
Urbanicity (binary)	0.6	0.49
% EcD	78.3	16.6
% LEP	41.4	20.6
% SpEd	6.9	3.1

Figure 6. Distribution of percentages of school-level demographics for the 110 schools selected in this study. ED - Economically Disadvantaged; LEP - Limited English Proficiency; SE - Special Education

Table 2 summarizes the first set of school-level demographics obtained from TEA sources, including the percentage of students at the school who are classified as (1) Economically Disadvantaged (EcD), as (2) Special Ed (SpEd) or as (3) Limited English Proficiency (LEP), as well as (4) the urbanicity of the school. These terms are defined by the State of Texas as follows [40]. Students are classified as EcD if they qualify for free or reduced-price meals under the National School Lunch and Child Nutrition Program, and it is worth noting that a large proportion (avg = 40%) of Texas public school students qualify for this status [40]. SpEd classifications are given to students who qualify for services for cognitive, emotional, or physical disabilities. LEP status is conferred for students whose primary home language is not English and who also fail to meet proficiency standards as established by either an approved testing measure or by a Language Proficiency Assessment Committee (LPAC). Finally, the TEA classifies a school district as urban (or not) [41] based on whether its school district (a) is located in a county with a population of at least 960,000; (b) has the largest enrollment in the county or its enrollment is greater or equal to 70% of county's

largest district. As seen in Table 2 and Figure 6, we have a diverse set of schools along these dimensions.

We also considered school-level data on the percentage of students representing major ethnic/racial groups. As Table 3 shows, Hispanic students are by far the largest group in these schools (mean = 63.5%), followed by African American students (mean = 17.5%), White students (mean = 13.5%) and then Asian students (4.5%), but as Figure 7 the schools show considerable variance in terms of this composition. To avoid noisy results, this analysis considers only groups that constitute at least 5% of the student population: Hispanic, African American, White and Asian.

Table 3. Standard deviation (SD) of the school-level percentages of ethnicities. Categories constituting less than 5% of the data were excluded from further analysis.

	Mean	SD
% Hispanic	63.5	24.5
% African American	17.5	17.8
% White	13.1	16.2
% Asian	4.5	7.8
% American Indian*	0.36	0.4
% Pacific Islander*	0.04	0.1
% Two or More Races*	1	1

Figure 7. Distribution of percentages of school-level ethnicities for the 110 schools selected in this study. H - Hispanic; AA - African American; W - White; A - Asian; AI - American Indian; PI - Pacific Islander; TR - Two or races

5. ANALYSIS

Our data exploration (Section 4) suggests that help-seeking behavior, math performance, math self-concept, and demographics each vary by school. Thus, we conduct a two-step data analysis to explore how help-seeking behavior might differ based on student demographics, while controlling for performance and motivational measures.

In the first step, we determine how closely students' math performance (and self concept measures) correlate to their hint

usage, within each school, using Spearman ρ correlations due to non-normality in the data. That is, we produce three new measures for each student, the correlation between hint use and performance on A-level problems, the correlation between hint use and the pre-year survey of self concept, and the correlation between hint usage and the post-year survey of self concept.

In the next step, we determine whether the differences in these correlations are themselves correlated to school-level demographics. Note that in the first step, the unit of analysis for the correlations is the student, but in the second step, the unit of analysis is the school. We conduct two-tailed tests to report the significance levels.

6. RESULTS

6.1 Help-Seeking and Student Outcomes

Figure 8 summarizes the results for our study, showing the distribution of correlations across schools between students' hint usage and their math performance and math self-concept (taken once at the beginning (pre) and again at the end of the year (post)).

Figure 8. Distribution of correlations across schools between students' hint usage and outcomes.

6.1.1 Help Seeking and Math Performance

Clustering students by schools allows us to see that the relationship between hint usage and math performance differs in ways that might be missed if this aggregation were not used. This is true even when demographic descriptions are not used to describe the data.

Specifically, when student measures are aggregated at the school level, we see that the correlation between hint usage and math performance ranges from -0.39 to 0.40 ($SD = .18$). In contrast, when we do not aggregate students into school-level populations (instead treating them all as a single population), there is not a significant relationship between hint usage and math performance ($\rho = -0.008$, $p = 0.44$).

6.1.2 Help Seeking and Math Self Concept

Like math performance, math self concept also shows signs of sub-population differences. When students are aggregated into school-level populations, the correlations between hint usage and math self-concept show a relatively wide range.

For pre-year surveys, the correlation ranges from -0.14 (students with lower self-concept are most likely to use hints) to 0.19

(students with higher self concept are most likely to use hints), and an even wide range is found for post-year survey correlations (-0.27 to 0.30). In contrast, when the students in this data were treated as a single population, the correlations were non-significant ($\rho = -0.008$, $p = 0.442$) for pre and $\rho = -0.007$, $p = 0.77$ for post).

6.1.3 Summary of Help Seeking Variance

There is considerable variance in the school-level correlations between hint usage and student outcome measures ($SD = 0.18$ for math performance, $SD = .084$ for pre-year self concept, $SD = 0.118$ for post-year self concept). This variance indicates that students likely have different motivations for using hints, and they be more effectively used by some student populations than by others.

As seen in Figure 8, the median of the correlations is centered close to zero. For these schools, there is no association between hint usage on student outcomes. Figure 8 also shows that the distribution of these correlations is not skewed, meaning that hint usage is not universally positively or negatively associated with student outcomes across schools.

The schools at the tail ends of these distributions are interesting case studies. They represent the cases where hint usage has either a notably high positive correlation or a notably high negative correlation with our outcome measures. In schools where there is a high positive correlation between these variables, the use of hints appears to be beneficial, but the converse is true for those schools that have high negative correlations. As such, it becomes important to understand what demographics are involved in order to address any potential disparate impacts of the hint function in the system.

6.2 The Influence of School Demographics

School-level demographic variables help to capture some of the variance in the relationship between hint usage and the student outcomes measured in this study (math performance and math-self concept). These findings are summarized in Tables 4 and 5.

Table 4. Correlations between school-level demographics and the correlations resulted between students' math performance and interaction features. p-value in parenthesis. Significant correlations in bold.

	Correlation between number of hints and		
	Math performance	self concept Pre	self concept Post
Urbanicity	0.292 (0.002)	0.130 (0.564)	0.080 (0.729)
%EcD	0.256 (0.007)	0.182 (0.417)	-0.288 (0.205)
%LEP	0.314 (0.001)	-0.452 (0.035)	-0.565 (0.008)
%SE	-0.002 (0.982)	0.463 (0.030)	0.444 (0.044)

Table 5. Correlations between school-level ethnicity and the correlations resulted between students' math performance

and interaction features. p-value in parenthesis. Significant correlations in bold.

	Correlation between number of hints and		
	Math performance	Self concept Pre	Self concept Post
% Hispanic	0.094 (0.329)	0.123 (0.587)	-0.153 (0.507)
% African American	0.054 (0.579)	-0.260 (0.243)	-0.174 (0.451)
% White	-0.194 (0.042)	0.103 (0.647)	0.095 (0.683)
% Asian	-0.037 (0.703)	-0.071 (0.753)	-0.107 (0.644)

6.2.1 School-level Demographics, Help Seeking, and Math Performance

As Table 4 (above) shows, the relationships between hint usage and math performance differ significantly in terms of the school's urbanicity ($\rho = .292$, $p = .002$) as well as differences in the percentage of students who are economically disadvantaged (EcD; $\rho = .256$, $p = .007$) and limited English proficiency (LEP; $\rho = .314$, $p = .001$). Specifically, the association between higher hint usage and math performance is positive among students from urban schools than students from rural or suburban schools. Schools with higher percentage of students who are economically disadvantaged (EcD) or limited English proficiency (LEP), show the same trends. Conversely, rural and suburban schools show an inverse relationship between hint usage and math performance, suggesting that these students may be using hints ineffectively.

However, as Table 5 shows, other demographic categories that are often considered in educational research, namely ethnicity, are not particularly useful in this context. Schools with smaller populations of White students are more likely to show a positive relationship between hint use and math performance, whereas this relationship is more likely to be negative in schools with larger populations of White students. However, neither the percentage of African American students (which tends to be relatively small in the state of Texas and in this sample in particular) nor the percentage of Hispanic students (which tends to be quite large) is correlated with this relationship.

6.2.2 School-level Demographics, Help Seeking, and Math Self Concept

School-level demographics are less helpful in explaining the relationships between hint usage and math self concept. The relationships between hint usage and math self concept differ significantly in terms of the percentage of students with limited English proficiency ($\rho = -.452$, $p = .035$ for pre; $\rho = -.565$, $p = .008$ for post), and the percentage of students in special education ($\rho = .463$, $p = .030$ for pre; $\rho = .444$, $p = .044$ for post)). Specifically, in schools that serve a higher percentage of LEP students, there is a negative correlation with hint usage and self concept. Whereas, hint usage is more common among students with high self concept in schools that serve fewer LEP students. This finding is somewhat stronger for the end of year surveys than

the start of year surveys. The opposite pattern is shown among schools that serve a higher percentage of SpEd students. In these schools, there is a positive correlation between hint usage and self concept, where as that relationship is negative in schools that serve fewer SpEd students. This relationship is consistent across the start of the year and end of the year surveys.

Other demographic factors from Table 4 that were predictive of the relationship between help seeking and math performance, namely urbanicity and EcD, were not significant for the relationship between help seeking and math self concept. School-level descriptions of ethnicity (Table 5) also did not help to explain the variance between math self concept and hint usage.

7. DISCUSSION

7.1 Overview of Results

Hint-seeking behaviors have been a source of interest among EDM researchers since the early days of the field, yet understanding which hints are effective, to whom, and under what conditions remains a somewhat elusive task.

A large part of answering these questions likely lies in understanding what motivates a student to seek help. Ideally, we would like students to use these functions to improve their understanding of the material, but as these results show, students who are struggling do not always make use of available resources (e.g., in schools where low performers are not requesting as many hints).

However, within this data—which studies students in the same state using the same mathematics learning system—there are also schools where low-performing students are requesting lots of hints. If these students are benefiting from this hint usage, it is not measurable with the variables considered in this study. This finding suggests that the hints could be less effective at helping these particular students to learn the material.

At least part of this variance seems to be related to school-level demographics, but interestingly, the schools where hint usage appears to be most advantageous are those that enroll larger numbers of students who would typically be thought of as disadvantaged by the school system. That is, schools with fewer LEP students are more likely to have low performers who are requesting lots of hints. Schools with fewer students receiving free or reduced price lunch are more likely to have low performers who are requesting lots of hints. Schools in large urban centers are less likely to have low performing students who are requesting lots of hints.

The relationship between hint usage and self-concept is also complicated. Students in schools that serve more LEP students tend to show a negative relationship between self concept and hint usage. That is, those students who are unsure of themselves are asking for more hints (in those schools). However, in schools that serve more SpED students, the relationship between self concept and hint usage is negative. It is also possible that the smaller number of students sampled for self concept (compared to math performance) made it more difficult for these relationships to emerge.

Ethnic population differences were not particularly revealing in this study, and it is not entirely clear why. It is possible that, say, the LEP findings are strong enough to warrant further divisions to the subpopulations included in this study, a possibility that has not yet been explored in this data. However, it is also possible that some of the linguistic differences that influence classroom practices different ethnic groups within the United States (e.g.,

[19])—practices that may include figuring out how to ask for help—are less relevant in an online context like Reasoning Mind where the student is simply pressing button to request a hint.

Gender was not investigated in the current paper, as public schools generally have balanced gender distributions (as was the case in this dataset), leading to limited power to observe any difference that might exist. This leads to a more general point. It would be beneficial to analyze the impact of demographics at the student level, both to replicate the relationships seen here and to study whether students who are outliers in their own schools have different patterns. However, collecting student-level data is not always feasible, and this study has demonstrated that school-level aggregates can likely improve our efforts to better capture variance in help-seeking behaviors.

7.2 Implications to ITS Designers

One of the main implications of this paper to ITS designers is that a universal design that focuses on improving student outcomes while ignoring individual or group differences might not be a fair design consideration. Personalization in help-design has primarily focused on student cognition to provide “in-context” hints based on the pedagogical content. We suggest expanding the definition of “in-context” to include broader contextual factors that impact student outcomes.

To illustrate this, let’s take the example of LEP. As stated in Section 6.2, there is an inverse influence of help-seeking and the two student outcomes (performance vs. self concept). In schools with a higher percentage of limited English proficient students, higher hint usage is associated with high math performance but low math self-concept. On the other hand, in schools with more native English speakers, higher hint usage is associated with low math performance but high math self-concept. This is an interesting case of conflict for ITS designers to investigate further. Is the text-heavy nature of the hints contributing to this finding? Is it that while limited English proficient students use hints to improve on their math skills, the cognitive load in processing more verbal content is causing a negative impact on their self-efficacy? Such investigations could open up opportunities for design innovations to better support students. Would it help to use multiple representations (visual, auditory, symbols) and give autonomy to the students to make the choice? In summary, including school-level demographics to the analysis of complex constructs like help-seeking is an important step in appropriately situating the design decisions to the student context.

7.3 Limitations and Future Work

We acknowledge that there are other socio-cultural aspects that influence a student’s engagement and learning with an ITS. In the case of students’ help-seeking behavior, the perceptions of help-seeking within their classroom (peers, teachers) and outside (family, friends) can be influence student choices. While this paper focuses on broadly-defined school-level demographics, we believe that it would be beneficial to look at other influencers from the student’s social context. For instance, the pedagogical practices of the teacher in the math classroom could influence what students perceive as appropriate help-seeking.

Within Reasoning Mind Foundations, specifically, teachers are able to explicitly choose to design which problem types to assign to their students, in line with their pedagogical goals and perceptions of the appropriate level of difficulty. These choices likely reflect the classroom culture they are hoping to foster—including the degree to which they encourage students to attempt new skills and persevere in the face of challenges. There is an

opportunity to explore this data to study the impact of teacher choices on the relationship between help-seeking and student outcomes.

More broadly, the priorities of the school district and state might also impact the pedagogical choices made in schools. Teachers’ choices are influenced by public policy. Shortly after the completion of our data collection, Texas issued letter grades (A-F) [42] to its school districts based on a complex formula involving overall student performance on standardized exams, overall year-to-year improvement, and improvement for specific sub-groups. These ratings were generally lower in districts with higher rates of economically disadvantaged students, creating different degrees of pressure where demographics differ. The pressure of performing well (as measured by standardized tests), in many cases with limited resources, could influence what is being prioritized as the goal of math learning in these schools. While quantifying these factors to include in an analysis is not straightforward, these factors no doubt drive the type of differences that are seen between schools with different demographics.

8. CONCLUSION

Self-regulation is an important aspect of successful learning. Intelligent Tutoring Systems like Reasoning Mind Foundations provide a unique opportunity for students to practice self-regulation by taking control over their choices in the learning environment. Help-seeking is a particularly relevant SRL process within this type of learning system, given the prominence of hints in ITSs. In this paper, we demonstrate that school-level demographics can have a significant influence on the relationships between students’ help-seeking behavior and student outcomes. In doing so, we question the prevailing assumption that complex constructs like help-seeking can be considered without also considering student context. This calls for greater consideration within our field of social, cultural, and economic influencers outside cognition.

Amidst the mixed results from empirical studies on the effectiveness of hints, Aleven and colleagues [4] continue to recommend the use hints in ITSs and suggest making four key methodological distinctions when studying interventions designed to promote help-seeking - (1) effects on learning in the same learning environment versus a new environment; (2) effects on current learning versus future learning; (4) effects on learning in the same domain versus another; (3) effects on SRL process versus domain-level learning. We propose to extend upon the list of these methodological considerations, suggesting that researchers also (5) explore the effects of help-seeking designs in one demographic context versus another. We make this proposal while fully understanding both the practical challenges elaborated in the introduction and the definitional issues elaborated in Section 7. However, as we can see that such demographic effects are present even within a single U.S. state (albeit one of the larger and more diverse U.S. States), it is worth considering the ways in which different groups of people may attach different meanings to the behavior of help seeking. In particular, research should consider the ways in which help-seeking might be interpreted as an imposition or as an admission of failure, since, as we discussed in Section 2, these interpretations likely vary from one culture to another. By considering demographics in our research on help-seeking—and on SRL in general—we increase the likelihood that our findings will apply to the full diversity of learners using ITSs and related systems today.

9. ACKNOWLEDGMENTS

ABSTRACT

Open-ended learning environments (OELEs) allow students to freely interact with the content and to discover important principles and concepts of the learning domain on their own. However, only some students possess the necessary skills for efficient and effective exploration. Guidance in the form of targeted interventions or feedback therefore has the potential to improve educational outcomes. A promising approach for adaptation in OELEs is the design of interventions based on the detection of characteristic learning behaviors through offline clustering, followed by a real-time classification of new students. In this paper, we explore the possibility of using recurrent neural network (RNN) models for this online classification task. We extensively evaluate the predictive performance of different variants of RNNs, namely long-short term memory models and gated recurrent units, and different architectures on a data set collected from an exploration-based educational game. We also compare the prediction accuracy of the different RNN models to the performance of traditional classifiers on the same data set. Our results demonstrate that RNNs perform similar or better than traditional methods regarding early classification and therefore constitute a promising alternative for the online classification of new students.

Keywords

recurrent neural networks, online classification, exploration environments, learning behavior

1. INTRODUCTION

Over the last years, there has been a rise in OELEs such as educational games or simulations. These environments allow students to freely interact with the content and (ideally) infer the concepts and principles of the learning domain through their exploration. However, previous research [20, 31, 24] has demonstrated that few students possess the problem solving and inquiry skills necessary to efficiently and effectively explore the space. Individualized guidance in the

form of adaptive interventions or feedback therefore have the potential to improve students' exploration strategies and at the same time optimize the educational outcomes.

Traditionally, adaptation in computer-based learning environments has been based on the predictions of the student model. A large body of work has focused on developing student models that are able to accurately represent student knowledge. One of the most popular student modeling approaches is Bayesian Knowledge Tracing (BKT) [8], a technique that has been constantly refined and improved over the years, e.g., [34, 35]. Other widely used approaches are based on item response theory, such as the Additive Factors Model [5, 6] and Performance Factors Analysis [28]. Furthermore, dynamic Bayesian networks, e.g., [13, 18] have been used to model student knowledge. All of these approaches are based on the assumption that the knowledge of the student can be represented through a set of skills (knowledge components) and that we can infer the knowledge about a specific skill based on students' answers to tasks associated with this skill. OELEs do not fulfill these criteria as they (usually) do not provide specific sequences of tasks or explicitly define knowledge components. Therefore, the introduced student modeling techniques cannot be (directly) applied to such environments.

A prominent idea in the literature is to provide adaptation based on detected (and analyzed) learning behaviors. This idea has been formalized into a user modeling framework [15]: First, offline clustering is used to identify different types of student behaviors. The adaptive components of the environment are then designed with respect to the different behaviors found. Second, an online classification algorithm assigns new students to one of the clusters (and the corresponding intervention) in real time. A large amount of previous research has focused on the offline clustering part of the framework, applying clustering approaches to identify different types of learners [25, 3, 10]. [12] have represented student activity patterns in massive open online courses (MOOCs) using behavior state-transition graphs and demonstrated that the extracted patterns can be interpreted. Other work assessed students' problem solving behaviors in a game-based learning environment [32]. The full framework has been successfully applied to an environment for learning common artificial intelligence algorithms [15]. Other researchers [16] have used the framework to predict the mathematical learning patterns of students. Recently, the framework has been used to build student models for a more complex simulation of electric circuits [11]. To summarize, the presented research has mostly focused on offline clustering or the appli-

Tanja Käser and Daniel L. Schwartz "Exploring Neural Network Models for the Classification of Students in Highly Interactive Environments" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 109 - 118

cation of the framework to different learning domains, performing online classification using standard algorithms such as k-nearest neighbor [2].

Recurrent neural networks (RNN) have been successfully used for a variety of sequence classification problems such as sentiment analysis, e.g., [23] and video, e.g., [9]. RNNs have also been used in the educational community, for example to model student knowledge [30], to provide personalized recommendations in MOOCs [27], or to improve sensor-free affect detection [4]. Furthermore, RNNs have also been employed for classification problems. [26] suggested the use of long-short term memory (LSTM) models to classify learner behavior from touchscreen data. Other work [1] used LSTMs for the classification of problem-solving behaviors.

In this paper, we explore the use of RNNs for online classification: we assume the offline clustering solution to be given and train different classifiers to predict the cluster label of a new student early on during interaction with the OELE. We hypothesize that the ability of RNNs to handle sequences of arbitrary length, allowing them to accumulate the relevant information over each time step, may benefit the online classification task. We investigate different types of RNNs, varying the models along three dimensions: the internal node structure used (LSTMs and gated recurrent units (GRU)), the depth of the network (number of layers), and the number of nodes in the hidden layers. We also train the models to either predict the whole sequence, i.e., outputting the cluster label at each time step, or only predict the cluster label at the end of the sequence. The former approach has the advantage that the model is able to predict the cluster label at any point in time. The latter approach requires training different models to make predictions at specific time points, but enables the models to optimize predictions for the given point in time. We extensively evaluate and compare the predictive performance of all the different RNN models on a data set collected from an OELE [17]. Our results demonstrate that RNNs trained to predict the cluster label at each time step reach a similar predictive performance in early classification as the RNNs trained to predict the cluster label at the end of the sequence. Furthermore, despite the smaller number of parameters, GRU models tend to achieve a classification accuracy similar to LSTM models. We also compare the RNN models to traditional classifiers on the same data set. Our findings show that the RNN models perform similarly or better than the traditional approaches regarding the prediction of cluster labels early in the game. Earlier prediction of cluster labels allows to provide targeted guidance sooner. We therefore conclude that the use of RNNs for the online classification of student types is promising.

2. DATASET

The data set at hand was collected from a short interactive game aiming at assessing students' exploration choices.

Training Environment. *TugLet* is an interactive game designed to assess students' exploration behavior. The topic of the game revolves around a tug-of-war. Players can choose between two modes (illustrated in Fig. 1): they can engage in inquiry by simulating tug-of-war set-ups (*Explore*) or they can try to predict the winning side of specific tug-of-war set-ups and receive right-wrong feedback (*Challenge*). The

Figure 1: Snapshots of *Explore* (top) and *Challenge* modes (bottom). In *Explore* mode, children can set-up different tug-of-war teams and observe the outcome. In *Challenge* mode, children have to determine the winning side of specific tug-of-war set-ups.

Challenge mode consists of a maximum of eight problems ordered by increasing difficulty. The eight problems consist of one very easy question followed by two easy questions, two medium questions, and three difficult questions. If the student answers a problem incorrectly, (s)he is put back into *Explore* mode. The student is however free to choose to go back to the *Challenge* mode at any point in time. The game is over after players solve eight problems in a row correctly. The learning goal of the game, which is not revealed to the player, is to discover the mathematical principles underlying the tug-of-war.

Data Set. The data set consists of log files of 229 students attending the 8th grade of two different middle schools. The total number of observations in this data set is 10'258. One observation corresponds to either one set-up tested in *Explore* mode or one question answered in *Challenge* mode. The length l of the observation sequences varies between $l = 12$ and $l = 127$. All students in this data set managed to pass the game.

Clustering Solution. Previous work [17] has shown that the learning outcome (measured by an external posttest) is

not only influenced by students' exploration choices (*Explore* vs. *Challenge*) but also by the quality of their inquiry strategies. It was furthermore shown [19] that students can be grouped into six different clusters based on these detected strategies. These clusters can be semantically interpreted: cluster 1 captures students who systematically explore and try to understand the mathematical principles behind the tug-of-war. Cluster 3 consists of students who pass the game fast by only using *Challenge* mode. Students in cluster 6 also do not explore, but take a long time to pass the game. Students in cluster 4 on the other hand simulate many different tug-of-war configurations in *Explore* mode, without success. Cluster 2 lies in-between clusters 1 and 3, and exploration behaviors in cluster 5 are a mix between those in cluster 3 and cluster 6. The clusters are not only correlated to performance in an external posttest, but also predict academic achievement more broadly [19].

The features serving as an input for the clustering are extracted by level: children need to answer eight *Challenge* questions in a row correctly to pass the game and therefore the game can be divided into eight levels. Level n is reached the first time the student answers exactly n questions in a row correctly. The features used for clustering consist of the following cumulative counts extracted for level $n \in [1, 8]$: the number of *Challenge* problems NC_n needed to reach level n , the total number of tug-of-war set-ups NE_n simulated in *Explore* mode before reaching level n , and the number of tug-of-war set-ups NSE_n simulated in *Explore* mode which are classified as reflecting systematic inquiry (see [17] for a definition of systematic inquiry) until reaching level n . Therefore, the input features used for the clustering are $\mathbf{NC} = [NC_1, \dots, NC_8]$, $\mathbf{NE} = [NE_1, \dots, NE_8]$, and $\mathbf{NSE} = [NSE_1, \dots, NSE_8]$. The cluster solution is then found by computing the pair-wise dissimilarities between all students for each feature using the Euclidean distance as a similarity measure and subsequently performing a pair-wise clustering [14]. The optimal number of clusters is determined by the Bayesian Information Criterion (BIC) [29]. In the following, we will use the presented clustering solution as ground truth for our classification task.

3. ONLINE CLASSIFICATION OF NEW STUDENTS

Ideally, the output of the clustering algorithm enables us to characterize different student behaviors and to design interventions or feedback based on the detected behaviors. Ideally, we are also able to characterize the performance of new learners in real time in order to deliver a targeted intervention as soon as possible. The corresponding framework is illustrated in Fig. 2. In the case of our data set, students assigned to cluster 4 might for example get hints on how to explore systematically, while students from cluster 3 will be prompted to use *Explore* mode in order to figure out the principles governing the tug-of-war.

RNN models are a family of neural network models able to handle sequences of arbitrary lengths. They are especially suited for time-series data and are able to represent the relevant information over a sequence of time steps. We therefore adapt different types of RNNs for the online classification task (marked in dark blue in Fig 2). RNNs map a sequence of input features $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_T$ to a sequence of output features $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_T$. They maintain a sequence of hidden states $\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_T$. These hidden states capture

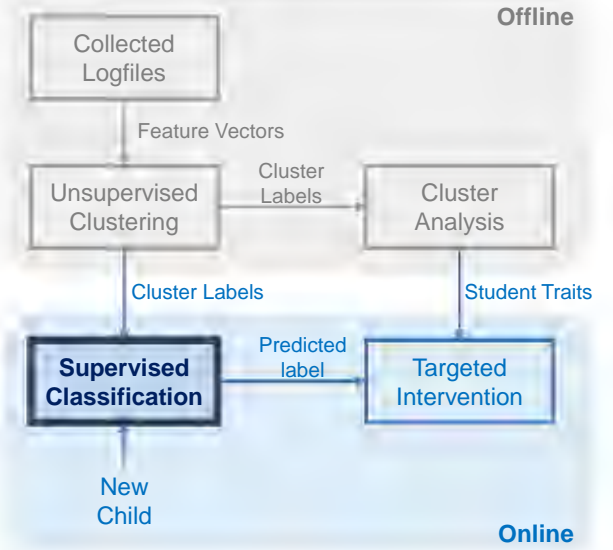

Figure 2: Students are clustered offline and targeted interventions are designed based on the (semantic) cluster interpretation. New students are then classified online. In this paper, we focus on the online classification task (marked in dark blue).

Figure 3: Simple RNN unrolled over T time steps. \mathbf{x} denotes the input feature vectors, \mathbf{y} denotes the output feature vectors and the hidden states are represented by \mathbf{h} .

relevant information from past observations which will influence future predictions. Figure 3 shows an illustration of a simple RNN model.

3.1 Long-Short Term Memory Classification

Long-short term memory (LSTM) models are a powerful modification of the RNN architecture.

Specification. LSTM models replace each hidden state \mathbf{h}_t by an LSTM cell unit with additional gating parameters. These parameters determine when to forget or retain previous information. The update equations of an LSTM are as follows:

$$\mathbf{f}_t = \sigma(W_{fx}\mathbf{x}_t + W_{fh}\mathbf{h}_{t-1} + \mathbf{b}_f) \quad (1)$$

$$\mathbf{i}_t = \sigma(W_{ix}\mathbf{x}_t + W_{ih}\mathbf{h}_{t-1} + \mathbf{b}_i) \quad (2)$$

$$C'_t = \tanh(W_{Cx}\mathbf{x}_t + W_{Ch}\mathbf{h}_{t-1} + \mathbf{b}_C) \quad (3)$$

$$C_t = \mathbf{f}_t \times C_{t-1} + \mathbf{i}_t \times C'_t \quad (4)$$

$$\mathbf{o}_t = \sigma(W_{ox}\mathbf{x}_t + W_{oh}\mathbf{h}_{t-1} + \mathbf{b}_o) \quad (5)$$

$$\mathbf{h}_t = \mathbf{o}_t \times \tanh(C_t) \quad (6)$$

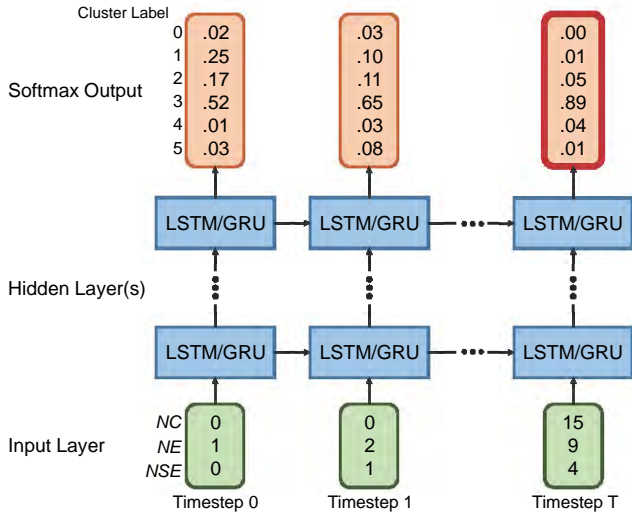

Figure 4: RNN model (LSTM or GRU units) with n hidden layers for an example student over T time steps. The input vector \mathbf{x}_t contains the counts NC_t , NE_t , and NSE_t at each time step t . The output vector $\hat{\mathbf{y}}_t$ can be interpreted as a probability distribution over the different cluster labels.

Here, \mathbf{f}_t , \mathbf{i}_t , and \mathbf{o}_t represent the forget, input, and output gates of the LSTM cell unit C_t . C'_t denotes an intermediate candidate cell state. The different weight matrices are described by W and the \mathbf{b} stands for bias.

Modeling. For our task, the input vector \mathbf{x}_t encodes the clustering features at each time step t . We input the counts for each time step t , i.e., $\mathbf{x}_t = [NC_t, NE_t, NSE_t]$. Let us assume that a hypothetical student m tested three different set-ups, the first two being random trials and the third one being systematic, followed by answering two *Challenge* questions. The input features for this student over the five described time steps are as follows: $\mathbf{x}_{m,1} = [0, 1, 0]$, $\mathbf{x}_{m,2} = [0, 2, 0]$, $\mathbf{x}_{m,3} = [0, 3, 1]$, $\mathbf{x}_{m,4} = [1, 3, 1]$, $\mathbf{x}_{m,5} = [2, 3, 1]$. Figure 4 details T time steps of an example student.

The output vectors $\hat{\mathbf{y}}_t$ represent the (predicted) cluster labels of the students: the output layer of the model uses the softmax function to normalize the vectors to sum to 1 such that the values within these output vectors can be thought of as probabilities for the different cluster labels (see Fig. 4). When training the model, we provide the cluster labels found during clustering as ground truth. Note that we use a one-hot encoding of the cluster labels, i.e. for a student m belonging to cluster $k = 2$, $\mathbf{y}_{m,t} = [0, 0, 1, 0, 0, 0]$. The chosen model predicts the cluster label of the student at each time step t , augmenting the amount of available data and increasing flexibility, as it allows to predict the cluster label of a specific child at any point in time. We denote this type of model as $LSTM_{Seq}$.

Note that $\mathbf{y}_{m,1} = \mathbf{y}_{m,2} = \dots = \mathbf{y}_{m,T}$ for all students m , because during clustering each student is assigned a fixed cluster label based on the whole sequence. Given that the cluster labels are fixed, we can also design the model to only output the cluster label at the end, i.e. train the LSTM to predict the cluster label at the end of a given input sequence. Instead of computing the training loss over the whole sequence, we calculate the loss only for the last output $\hat{\mathbf{y}}_T$ of the sequence (marked with red in Fig. 4). When using this type of model, we have to train a separate model for each

prediction time point. In our case, we will train separate models for each level. We call this model $LSTM_{End}$.

Stacking multiple LSTM layers (see hidden layers in Fig. 4) is another possible variation of the architecture, i.e., the vector \mathbf{h}_t of layer $n - 1$ serves as an input for layer n . Stacking layers adds levels of abstraction of input observations over time, for example enabling representation of the problem at different time scales. We will denote LSTM models with n hidden layers, where $n > 1$, as $LSTM_{Seq,n}$ or $LSTM_{End,n}$.

3.2 Gated Recurrent Unit Classification

Gated recurrent unit (GRU) models are another powerful modification of RNN models. In contrast to LSTMs, they are less complex, making training more efficient.

Specification. Similar to LSTM models, GRU models replace each hidden unit \mathbf{h}_t by a GRU cell unit with additional gating parameters. GRUs use update and reset gates, deciding what information should be passed to the output. The update equations of a GRU are as follows:

$$\mathbf{z}_t = \sigma(W_{fz}\mathbf{x}_t + W_{fh}\mathbf{h}_{t-1} + \mathbf{b}_z) \quad (7)$$

$$\mathbf{r}_t = \sigma(W_{ix}\mathbf{x}_t + W_{ih}\mathbf{h}_{t-1} + \mathbf{b}_i) \quad (8)$$

$$\mathbf{h}'_t = \tanh(W_{h'x}\mathbf{x}_t + r_t \times W_{h'h}\mathbf{h}_{t-1} + \mathbf{b}'_h) \quad (9)$$

$$\mathbf{h}_t = \mathbf{z}_t \times \mathbf{h}_{t-1} + (1 - \mathbf{z}_t) \times \mathbf{h}'_t \quad (10)$$

\mathbf{z}_t and \mathbf{r}_t represent the update and reset gate of the GRU cell unit. \mathbf{h}'_t denotes an intermediate candidate hidden state. The different weight matrices are described by W and the \mathbf{b} stands for bias.

Modeling. Just as for the LSTM models, the clustering features at each time step t are represented by the input vector \mathbf{x}_t , i.e., $\mathbf{x}_t = [NC_t, NE_t, NSE_t]$. The input sequence of an example student is given in Fig. 4. We also use the exact same description for the output layer of the GRU: the output layer of the model uses the softmax function to normalize the vectors to sum to 1 such that the values within the output vectors $\hat{\mathbf{y}}_t$ can be interpreted as probabilities for the different cluster labels (see Fig. 4). We again train a model on the whole output sequences of the students able to predict the cluster label at each time step t . We denote this model with GRU_{Seq} . We also train one GRU model per level, where we compute the loss of the model only for the last output $\hat{\mathbf{y}}_T$ of the sequence (marked with red in Fig. 4). We denote this model with GRU_{End} . Finally, similar to LSTM models, we can also stack GRU models on top of each other. We will call models with n hidden layers, where $n > 1$, $GRU_{Seq,n}$ or $GRU_{End,n}$.

4. EXPERIMENTAL EVALUATION

We evaluated the predictive accuracy of the variations of RNN models on the data set described in Section 2. We also compared them to the following popular traditional classifiers using the same data set: k-Nearest-Neighbor (kNN) and random forests (RF). While these classifiers are well tested and efficient to train, they require features being the same length for each student and therefore need to be trained for fixed points in time. RNNs on the other hand represent the relevant information over time, possibly enabling a more accurate classification of students early in the game.

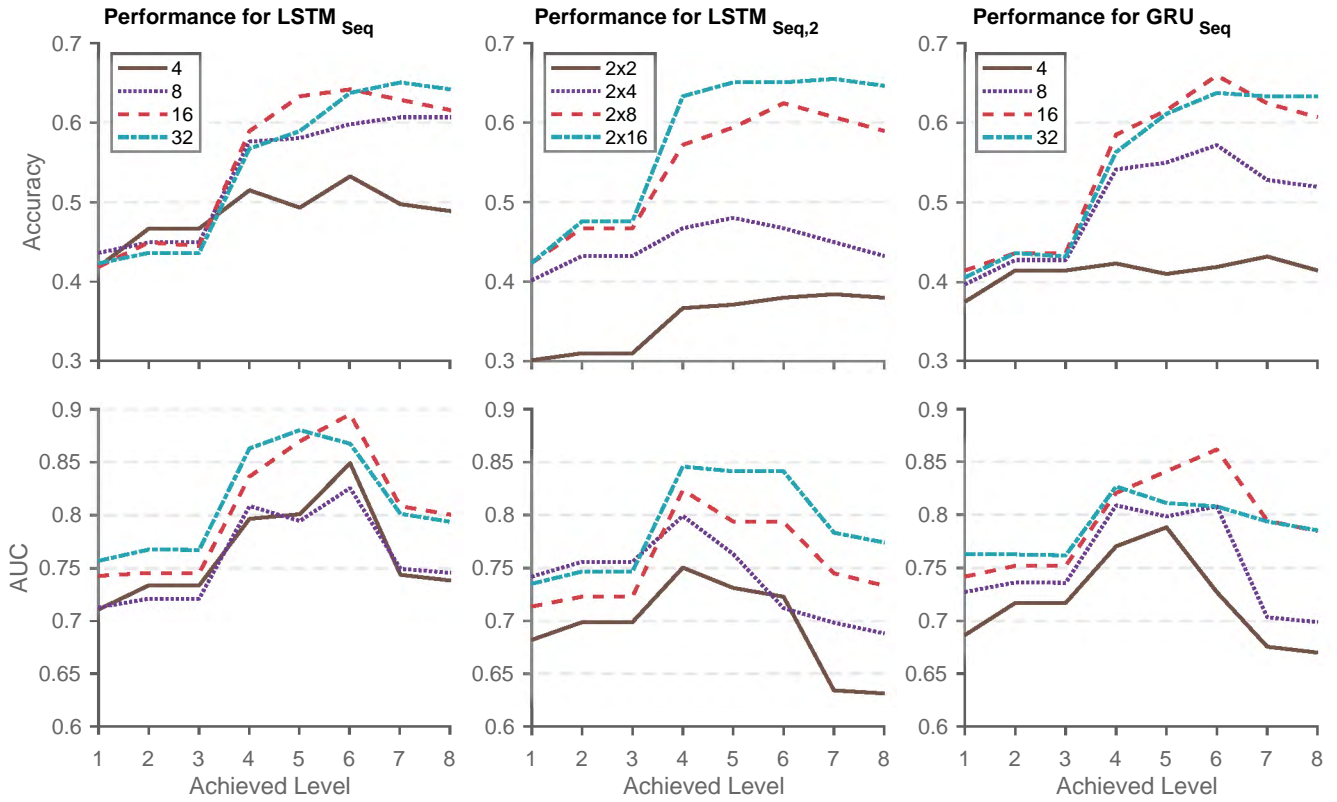

Figure 5: Accuracy (top) and AUC (bottom) of the $LSTM_{Seq}$, $LSTM_{Seq,2}$, and GRU_{Seq} models by achieved level. Both measures increase up to level 6 and stagnate or deteriorate afterward. This is probably due to the fact that the models are trained to predict the cluster label after each time step t , i.e. training loss is optimized over the whole sequence of observations.

Experimental Setup. We applied a train-test setting, i.e. parameters were fit on the training data set and performance of the methods was evaluated on the test data set. Predictive performance was evaluated using the accuracy as well as the micro-averaged area under the ROC curve (AUC). The accuracy is a measure that can be interpreted easily. The cluster solutions for both data sets are not balanced. We used the AUC as an additional performance measure as it is robust to class imbalance.

For all methods, we used a student-stratified (i.e. dividing the folds by students) 10-fold cross validation. Within each fold f , we re-clustered the students of the training data set of f to obtain the output features \mathbf{y} , i.e. the cluster labels, for training. We purposely did not use the original cluster labels from the solution found on the whole data set (including training and test data) for training, to prevent dependencies to the cluster labels of the test data set. The average cluster stability [22] between the 10 different training data sets and the original cluster solution was 0.87, i.e., on average 87% of the samples received the same label on the training data set as on the original data set. Therefore, 0.87 constitutes an upper bound for the accuracy of the classifiers.

All the RNN models were implemented using Keras [7] with Theano [33] as backend. Categorical crossentropy was used to calculate loss and ADAM was used as the optimizer. The models were trained for $e = 100$ epochs. For all types of RNN models, we used post-padding and masking to account for the different sequence lengths.

For the traditional classifiers, we trained one model for each

level n of the game. The input vector \mathbf{x}_n of each model therefore encodes the clustering features exactly at level n , i.e., $\mathbf{x}_n = [NC_n, NE_n, NSE_n]$.

We determined the optimal number k_o of nearest neighbors for the kNN classifier as follows: within each fold f , we randomly put 10% of the students from the training data set in a validation data set and selected the number of nearest neighbors $k_{o,f}$ yielding the best performance in terms of accuracy on this validation data set. We then predicted the cluster labels of the test data set using the labels of the $k_{o,f}$ nearest neighbors.

For the RF method, we trained $B = 100$ binary decision trees using bootstrapping with re-sampling ($r_f = 1.5 \cdot M_f$, with M_f being the number of samples in the training data set of fold f).

RNN Models returning a sequence of outputs. We varied the parameters of our RNN models outputting the whole sequence of cluster labels along three dimensions: the structure of the hidden layer(s) (LSTM or GRU), the number of hidden layers, and the dimension of the hidden state within a hidden layer. Specifically, we computed the predictive performance for the following models: a 1-layer LSTM ($LSTM_{Seq}$) with a d_h -dimensional hidden state where $d_h \in \{4, 8, 16, 32\}$, a 2-layer LSTM ($LSTM_{Seq,2}$) with a d_h -dimensional hidden state per layer where $d_h \in \{2, 4, 8, 16\}$, and a 1-layer GRU (GRU_{Seq}) with a d_h -dimensional hidden state where $d_h \in \{4, 8, 16, 32\}$. Figure 5 illustrates the predictive performance in terms of accuracy and AUC for the three

Figure 6: Categorical crossentropy of the LSTM_{Seq}, LSTM_{Seq,2}, and GRU_{Seq} models by the number of dimensions of the hidden state. The average test error begins to increase when using more than $d_h = 16$ hidden dimensions, while the training error still decreases.

different architectures by achieved level.

The LSTM_{Seq} models reach a poor accuracy when $d_h = 4$. There is also not much difference between the accuracy at level 1 (0.42) and at level 8 (0.49). The accuracy improves substantially when increasing the dimension of the hidden state to $d_h = 8$, $d_h = 16$, or $d_h = 32$. We especially observe a jump in accuracy between levels 3 (e.g., Accuracy₈ = 0.45) and 4 (e.g., Accuracy₈ = 0.58). For $d_h = 32$, there is a second jump between levels 5 (Accuracy₃₂ = 0.59) and 6 (Accuracy₃₂ = 0.64). These jumps in accuracy correspond to jumps in the difficulty of the *Challenge* questions: the eight problems consist of one very easy question followed by two easy questions, two medium questions, and three difficult questions. There is no increase in accuracy between levels 1 and 3 as most students passed these easy levels very quickly. We observe a similar picture for the AUC. The AUC increases with the number of dimensions d_h of the hidden state. Note that the AUC again jumps between levels 3 (e.g., AUC₈ = 0.72) and 4 (e.g., AUC₈ = 0.81).

For the LSTM_{Seq,2} models, predictive performance again increases with the number of dimensions of the hidden state within a layer. For this type of models, using a 2-dimensional hidden state or a 4-dimensional hidden state per layer leads to a low accuracy. Increasing to an 8-dimensional hidden state or a 16-dimensional hidden state per layer yields a large improvement in accuracy and these models also show a jump in accuracy between level 3 (e.g., Accuracy_{2x16} = 0.48) and level 4 (e.g., Accuracy_{2x16} = 0.63). The AUC also increases with an increasing number of dimensions d_h per hidden layer. The LSTM_{Seq,2} models' accuracy is in range with the accuracy of the LSTM_{Seq} models for $d_h = 16/d_h = 2x8$ hidden dimensions as well as for $d_h = 32/d_h = 2x16$ hidden dimensions. However, the LSTM_{Seq} models show a higher AUC than the LSTM_{Seq,2} models, e.g., for $d_h = 16/d_h = 2x8$ hidden dimensions (for example at level 5: AUC_{LSTM_{Seq}} = 0.87, AUC_{LSTM_{Seq,2}} = 0.79).

Performance of the GRU_{Seq} models in terms of accuracy shows the same trends over time as for the LSTM_{Seq} mod-

els. Again, employing a 4-dimensional hidden state results in a low accuracy. When increasing the number of dimensions of the hidden state to $d_h = 8$, $d_h = 16$, or $d_h = 32$, the models are able to capture the jump in difficulty between level 3 (e.g., Accuracy₈ = 0.43) and level 4 (e.g., Accuracy₈ = 0.54). The architecture employing a 16-dimensional hidden state also shows a jump in accuracy between level 4 (Accuracy₁₆ = 0.59) and level 6 (Accuracy₁₆ = 0.66). The AUC again increases with an increasing number of dimensions of the hidden state. Applying $d_h = 32$ instead of $d_h = 16$ hidden dimensions does generally not increase the AUC, and is even worse for some levels, e.g., for level 6 (AUC₁₆ = 0.86, AUC₃₂ = 0.81). Generally performance is in range with the performance of the LSTM_{Seq} models in terms of accuracy for $d_h = 16$ and $d_h = 32$ hidden dimensions. Again, the AUC for the LSTM_{Seq} models tends to be higher than the AUC for the GRU_{Seq} models, for example for $d_h = 16$ hidden dimensions at the peak level 6 (AUC_{LSTM_{Seq}} = 0.90, AUC_{LSTM_{GRU}} = 0.86).

The performance increase of all models with a higher number of hidden dimensions is as expected. However, the danger of overfitting increases with a higher number of parameters. While our training and evaluation methods have measures for overfitting, such as the crossvalidation, in place, we investigated the relation between the average training and test error of the different configurations and the number of dimensions d_h of the hidden state. Figure 6 illustrates the average categorical crossentropy on the training data sets and test data sets. We observe that the difference between training error and test error starts to get bigger with an increased number of hidden dimensions. Specifically, there is a kink in the test error at $d_h = 16/d_h = 2x8$ hidden dimensions for all models. We therefore conclude that $d_h = 16/d_h = 2x8$ is the maximum number of hidden dimensions that should be used for this data set.

RNN Models returning the last output in the sequence. We also trained a range of RNN models returning

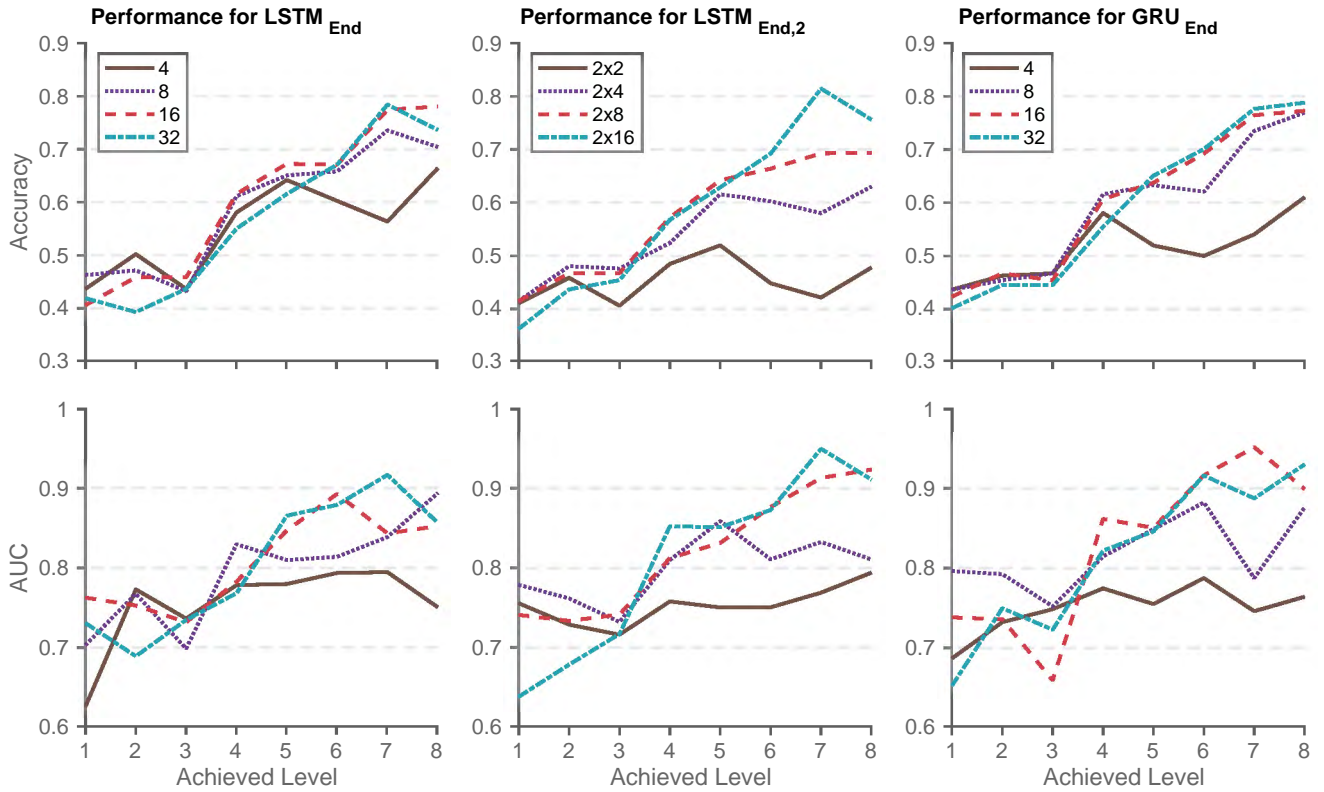

Figure 7: Accuracy (top) and AUC (bottom) of the LSTM_{End} , $\text{LSTM}_{\text{End},2}$, and GRU_{End} models by achieved level. Both measures increase over time and all models achieve a similar predictive performance for the higher numbers of hidden dimensions.

only the last output in the sequence, i.e. predicting the cluster label at the end of a given sequence. We varied the parameters of these models along the same dimensions as for the models predicting the whole sequence. Specifically, we computed the predictive performance for the following models: a 1-layer LSTM (LSTM_{End}) with a d_h -dimensional hidden state where $d_h \in \{4, 8, 16, 32\}$, a 2-layer LSTM ($\text{LSTM}_{\text{End},2}$) with a d_h -dimensional hidden state per layer where $d_h \in \{2, 4, 8, 16\}$, and a 1-layer GRU (GRU_{End}) with a d_h -dimensional hidden state where $d_h \in \{4, 8, 16, 32\}$. We trained one model for each level of the game. The predictive performance of all the models in terms of accuracy and AUC is illustrated in Fig. 7.

Similar to the models predicting sequences, the LSTM_{End} model achieves the lowest accuracy with $d_h = 4$. However, up to level 6, there is no big difference in accuracy between this model and the models with $d_h \geq 8$ hidden dimensions. All the LSTM_{End} models capture the jump in difficulty between level 3 and level 4. The models with higher-dimensional hidden states also capture the second jump happening after level 5. For $d_h = 16$, we for example see a jump in accuracy after level 3 (level 3: Accuracy = 0.46, level 4: Accuracy = 0.62) and a second jump after level 6 (level 6: Accuracy = 0.67, level 7: Accuracy = 0.77). Regarding the AUC, we observe superior performance of the models with $d_h = 16$ and $d_h = 32$ hidden dimensions after level 4. For these models, the AUC constantly increases until level 6 ($\text{AUC}_{16} = 0.89$, $\text{AUC}_{32} = 0.88$). As seen before, we do not observe any improvement in performance after level 6.

For the $\text{LSTM}_{\text{End},2}$ model, employing $d_h = 2$ hidden dimen-

sions per layer leads to the lowest achieved accuracy and there is also not much improvement over time. The models with $d_h > 2$ capture the increased difficulty after level 3 (e.g., level 3: $\text{Accuracy}_{2 \times 8} = 0.47$, level 4: $\text{Accuracy}_{2 \times 8} = 0.57$). Only the models using $d_h = 8$ or $d_h = 16$ hidden dimensions per layer manage to capture the second jump in difficulty (e.g., level 6: $\text{Accuracy}_{2 \times 16} = 0.69$, level 7: $\text{Accuracy}_{2 \times 16} = 0.81$). We observe a similar picture for the AUC: when using $d_h = 8$ or $d_h = 16$ hidden dimensions, there is a strong increase in AUC after level 3 (e.g., level 3: $\text{AUC}_{2 \times 8} = 0.74$, level 4: $\text{AUC}_{2 \times 8} = 0.81$) and after level 6 (e.g., level 6: $\text{AUC}_{2 \times 16} = 0.87$, level 7: $\text{AUC}_{2 \times 16} = 0.95$).

The accuracy plot of the GRU_{End} models looks similar to the accuracy plot of the LSTM_{End} models. Up to level 4, all models perform similarly (at level 4: $\text{Accuracy}_4 = 0.58$, $\text{Accuracy}_8 = 0.62$, $\text{Accuracy}_{16} = 0.61$, $\text{Accuracy}_{32} = 0.55$). For the higher levels, the model with $d_h = 4$ hidden dimensions shows the lowest accuracy. Using a model with an 8-dimensional hidden state nicely captures the jumps in accuracy between level 3 (Accuracy = 0.47) and level 4 (Accuracy = 0.62) and between level 6 (Accuracy = 0.62) and level 7 (Accuracy = 0.73). Increasing the number of hidden dimensions to $d_h = 16$ improves performance only from level 5 on (e.g., at level 6: $\text{Accuracy}_8 = 0.62$, $\text{Accuracy}_{16} = 0.69$). This model also captures the two jumps in accuracy. Using $d_h = 32$ hidden dimensions does not lead to any further improvements. The model employing a 4-dimensional hidden state performs worst for the AUC, with exception of level 3. When using $d_h = 16$ or $d_h = 32$ hidden dimen-

sions, the AUC again models the two jumps in difficulty (e.g., level 3: $AUC_{32} = 0.72$, level 4: $AUC_{32} = 0.82$, level 5: $AUC_{32} = 0.85$, level 6: $AUC_{32} = 0.92$). It also seems that using a higher number of hidden dimensions, i.e. $d_h > 8$, increases the stability of the AUC. With exception of the drop at level 3, the AUC of the model with $d_h = 16$ hidden dimensions nicely increases over time.

We again tested for overfitting, by comparing the average training and test loss of the different models. Just as for the models trained to predict the cluster label at each time step, we found that there is a kink at $d_h = 16$ hidden dimensions: while the training error still decreases for a higher number of d_h , the error on the test set increases. We therefore conclude that $d_h = 16$ is the maximum number of hidden dimensions that can be used.

‘Sequence versus End’. When comparing the RNN models trained for sequence prediction to the models trained to predict only the last output of the sequence, we observe that the performance plots show the same overall trends (see Fig. 5 and Fig. 7). For both types, predictive performance in terms of the accuracy is similar for the 1-layer LSTM and the 1-layer GRU models. The GRU_{Seq} model generally has a lower accuracy than the $LSTM_{Seq}$ model when using $d_h < 16$. The GRU_{End} model exhibits a lower accuracy than the $LSTM_{End}$ model only for $d_h = 4$. The models with two stacked layers, i.e. the 2-layer LSTM models, generally show a lower accuracy when employing a low number of hidden dimensions per layer (2×2 or 2×4).

For both the ‘sequence’ and the ‘end’ RNN models, all three model types achieve similar accuracies for $d_h = 8$ or $d_h = 16$ hidden dimensions. All RNN models show no improvement or even a drop in AUC after level 6. This effect is more pronounced for the models which are trained on the sequence, as their loss is optimized over the whole sequence. We further hypothesize that the length of the sequences at the higher levels might be too long for the RNN models to capture the relevant information, because even with the LSTM architecture, RNNs tend to struggle with very long data sequences. The main difference between the ‘sequence’ and the ‘end’ model is the larger increase of the accuracy with increasing levels. For example, for the $LSTM_{Seq}$ with $d_h = 16$ the accuracy at level 1 is 0.42 and the accuracy at level 7 is 0.63, while the accuracy of the $LSTM_{End}$ model with $d_h = 16$ is 0.41 at level 1 and 0.77 at level 7. Because the ‘end’ models are optimized to predict the last output of a sequence, they reach a higher accuracy at the end of the game (e.g. at level 8: $Accuracy_{GRU_{Seq},16} = 0.61$, $Accuracy_{GRU_{End},16} = 0.77$). The ‘sequence’ RNN models are optimal on average and therefore exhibit less variance over time and smoother accuracy and AUC curves. For the medium levels of the game, ‘sequence’ and ‘end’ RNN models perform similar in terms of accuracy and AUC.

All configurations exhibit a satisfying accuracy and a medium-high AUC for $d_h \geq 8$. As a comparison, a random classifier would achieve an accuracy of 0.17 and the accuracy of a classifier always predicting the majority label would be 0.32. The AUC of these two classifiers would be 0.5.

Comparison to traditional classifiers. We compared the predictive performance of selected RNN models to the predictive performance of the traditional classifiers. Because the RNN models show an increased performance with a

Figure 8: Accuracy (top) and AUC (bottom) of kNN, RF, $LSTM_{Seq}$, and $LSTM_{End}$ by achieved level. The RNNs achieve similar or better performance than the traditional classifiers up to level 6.

higher number of hidden dimensions, we used RNN models with the maximum number of $d_h = 16$ not resulting in overfitting for comparison. In case of the ‘sequence’ models, the $LSTM_{Seq}$ model achieved a similar accuracy, but a higher AUC than the two other model types for $d_h = 16$. We therefore selected the $LSTM_{Seq}$ model with $d_h = 16$ for comparison. In case of the ‘end’ models, the 1-layer LSTM and 1-layer GRU models achieved similar results, however, the LSTM models were better at predicting the jumps in difficulty. We therefore selected the $LSTM_{End}$ model with $d_h = 16$ for comparison. Figure 8 displays the accuracy and the AUC of the kNN classifier, the RF method, a 1-layer LSTM model for sequence predicting with $d_h = 16$ hidden dimensions ($LSTM_{Seq}$), and a 1-layer LSTM model for predicting the last output of the sequence with $d_h = 16$ hidden dimensions ($LSTM_{End}$).

We observe that the RNN models outperform the traditional classifiers for the first three levels regarding the accuracy (e.g., at level 3: $Accuracy_{kNN} = 0.38$, $Accuracy_{RF} = 0.43$, $Accuracy_{LSTM_{Seq}} = 0.45$, $Accuracy_{LSTM_{End}} = 0.46$). The same holds for the middle of the game, i.e. levels 4 – 6 (e.g., at level 5: $Accuracy_{kNN} = 0.57$, $Accuracy_{RF} = 0.63$, $Accuracy_{LSTM_{Seq}} = 0.63$, $Accuracy_{LSTM_{End}} = 0.67$). At the end of the game, the accuracy of the traditional classifiers is close to the stability of the clustering ($Accuracy_{kNN} = 0.85$, $Accuracy_{RF} = 0.83$).

For the RF approach and the two RNN models, we also computed the AUC (see Fig. 8 (bottom)). In contrast to the other three methods outputting probabilities for each cluster label, kNN just outputs the predicted cluster label and we therefore did not compute the AUC for this method. We observe that the $LSTM_{Seq}$ and the $LSTM_{End}$ models clearly outperform the RF method at the beginning of the game (e.g., at level 3: $AUC_{RF} = 0.71$, $AUC_{LSTM_{Seq}} = 0.75$, $AUC_{LSTM_{End}} = 0.73$). Also in the middle of the game between levels 4 and 6, the RNN models show a higher AUC than the RF method (e.g., at level 5: $AUC_{RF} = 0.82$,

$AUC_{LSTM_{Seq}} = 0.89$, $AUC_{LSTM_{End}} = 0.87$) with the exception of level 4. When looking at the whole sequence, we observe a similar picture as for the accuracy: the AUC of the RF method is clearly higher than the AUC of the RNN models (at level 8: $AUC_{RF} = 0.91$, $AUC_{LSTM_{Seq}} = 0.80$, $AUC_{LSTM_{End}} = 0.85$).

As already mentioned before we assume that the worse performance of the RNN models at the end of the game (level 7 and level 8) is due to the fact that the input sequences for the RNN models become too long. Note that while most students manage to reach level 5 within a reasonable time frame, the lengths of the complete sequences vary significantly between the students. The lower accuracy and AUC of the RNN models at the end of the game are not an issue in our case because we are interested in accurate predictions early in the game. While the RNN models show only a slightly increased accuracy in comparison to the traditional methods at the beginning and in the middle of the game, they consistently achieve a higher AUC up to level 6, demonstrating their robustness towards class imbalance.

5. DISCUSSION

OELs constitute a promising approach for learning. Ideally, the students learn the concepts and principles of a domain more deeply through exploration than if they are simply taught the principles and practice applying them. However, it has been shown that only a part of the students are able to effectively explore the space [20, 31, 24, 17]. Providing guidance to struggling students is therefore essential for educational success.

Because OELs allow the user to freely interact with the content, traditional student modeling approaches cannot directly be applied to provide adaptation to the student. Adaptation based on detected student behavior and strategies is therefore a promising approach. Previous work has used offline clustering to detect different student types, followed by online classification of new students [15, 16, 11].

In this paper, we focused on the task of online classification, i.e., predicting the student type (or behavior) early on during interaction with the environment to provide targeted guidance as early as possible. In contrast to previous work applying standard classifiers such as k-nearest-neighbor [15, 16, 11], we suggested the use of RNN models for the online classification task. While previous research has investigated the use of RNN models to classify the students according to their problem-solving behavior based on their whole sequence of interactions [1], to classify changing learner behaviors over time [26], or to detect affective states over time [4], we explored the possibility of using RNN models to predict a student's cluster label (fixed over time) as early as possible. We have extensively evaluated a variety of RNN models and compared their predictive performance to the performance of k-nearest neighbor and random forest classifiers. We have used the different levels of the game as specific time points for evaluation as they pose realistic time points for interventions. We have trained RNN models to predict the cluster label at each time step as well as RNN models optimized for predicting the cluster label at each level of the game.

Not unexpectedly, the RNN models trained per level as well as the traditional classifiers outperform the models trained for predicting the whole sequence at the higher levels (level 7 and 8) of the game. This is due to the averaging effect of the

performance of the 'sequence' RNN models: during training, the loss is computed for each time step of the sequence. Nevertheless, for level 4 and 5, which provide promising time points of intervention both in terms of accuracy of the different models as well as in terms of timing of intervention, the $LSTM_{Seq}$ model with 16 hidden dimensions reaches similar performance as the other approaches. While this model does not outperform traditional approaches regarding prediction accuracy, it provides the potential for further adapting intervention. As the model is able to predict the cluster label at each time step, it is possible to provide the intervention at different points in time for different students depending on how sure the model is about the cluster label of the student. [21] have for example used a simple heuristic to at each time step decide whether the model should continue to see further time steps before outputting a final decision. While exhibiting the same accuracy, classification happened on average at an earlier point in time. This earlier classification allowed to provide targeted interventions sooner.

While the $LSTM_{End}$ model with 16 hidden dimensions is also outperformed by the traditional classifiers at level 7 and 8 of the game, it shows a higher prediction accuracy than the kNN and RF classifiers for the first levels. Our results further demonstrate that the $LSTM_{End}$ model with 16 hidden nodes outperforms the RF classifier regarding the AUC. This is especially important, because the AUC is not biased by imbalanced data sets.

We have also investigated different architectures for the RNN models. Our results demonstrate no large difference in the performance of LSTM and GRU models. However, due to their lower complexity, GRU models are more efficient and take less time to train the LSTM models. While this was not an issue for our small data set, it should be considered when training on larger data sets.

Due to the relatively small number of samples, we were able to only train shallow models with one or two hidden layers, not fully exploiting the advantages of deep learning. Furthermore, we also had to keep the number of dimensions of the hidden state low. However, the results achieved on our small data set are promising and we assume that the RNN models would perform even better on larger data sets.

In the future, we plan to design and test targeted interventions for the different clusters. Furthermore, we will collect a substantially larger data set to enable the training of deep neural networks using raw feature input only. Finally, we also plan to design and train the classifier such that scaffolded interventions can be delivered.

ABSTRACT

Early prediction of student difficulty during long-duration learning activities allows a tutoring system to intervene by providing needed support, such as a hint, or by alerting an instructor. To be effective, these predictions must come early and be highly accurate, but such predictions are difficult for open-ended programming problems. In this work, Recent Temporal Patterns (RTPs) are used in conjunction with Support Vector Machine and Logistic Regression to build robust yet interpretable models for early predictions. We performed two tasks: to predict student *success* and *difficulty* during one, open-ended novice programming task of drawing a square-shaped spiral. We compared RTP against several machine learning models ranging from the classic to the more recent deep learning models such as Long Short Term Memory to predict whether students would be able to complete the programming task. Our results show that RTP-based models outperformed all others, and could successfully classify students after just *one* minute of a 20-minute exercise (students can spend more than 1 hour on it). To determine when a system might intervene to prevent incompleteness or eventual dropout, we applied RTP at regular intervals to predict whether a student would make progress within the next five minutes, reflecting that they may be having difficulty. RTP successfully classified these students needing interventions over 85% of the time, with increased accuracy using data-driven program features. These results contribute significantly to the potential to build a fully data-driven tutoring system for novice programming.

1. INTRODUCTION

Modeling student cognitive processes is highly complex since it is influenced by many factors such as motivation, apti-

tude, and learning habits. This is especially challenging for computer-based programming environments, because of the open-ended nature of programming. In this study, we focus on two important types of student modeling tasks to improve student experience in computer-based programming environments: 1) whether students will eventually succeed, and 2) at any given time, whether students need intervention. The interventions are more effective as we can predict earlier. Indeed, student modeling has been studied extensively for well-defined domains like algebra or physics [18, 17, 22]. For an ill-defined domain like programming, there are no pre-defined steps that students must take to complete a given program. Thus, it is hard to map the observations from students step by step. This makes the step-aligned models, like Bayesian Knowledge Tracing (BKT) [10], inappropriate for the programming domain.

Analyzing programming data often requires a way to represent a student's current state on a given problem. In the domain of programming, a student's state is typically represented by their current code, called a code-state. However, this representation leads to very large and poorly connected state spaces [14, 31], which makes it difficult to compare students and apply data-driven methods. Thus, in this study, we transformed student click-like log files into fixed feature sets. As shown in our prior work [38], this feature-state representation dramatically reduces the size of an open-ended programming state space, while creating semantically meaningful states. In this study, we explore both expert feature (EF) and data-driven feature (DDF) sets, and further compare their robustness on the two prediction tasks.

In recent years, deep learning models, specifically Recurrent Neural Networks (RNNs) and RNN-based models such as Long Short Term Memory (LSTM) [13] and gated recurrent unit (GRU) [9], have been shown to achieve state-of-the-art results in many applications with multivariate time series data including educational data. Such models enjoy several nice properties such as strong prediction of performance through deep hierarchical feature construction as well as the ability to effectively capture long-term temporal dependencies in time series data. Despite their extensive applications and great success, the open-ended nature in programming

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 119 - 128

state-space and various time intervals can pose enormous challenges for deep learning. More importantly, these deep learning models are often treated as “black box” models because of the lack of interpretability – they are particularly difficult to understand because of their non-linear nature.

On the other hand, Temporal Pattern-based approaches are designed to extract *interpretable, meaningful* temporal patterns directly from irregularly-sampled multivariate time series data. Recently, significant efforts have been made to develop and apply various pattern-based approaches to healthcare and shown to be effective. [7, 21]. However, as far as we know, temporal Pattern-based approaches have not been extensively investigated in the field of educational data mining especially for programming. In this work, we will directly compare one Temporal Pattern-based approach, Recent Temporal Patterns (RTPs) [7] against a series of baseline models including three classic machine learning models: k-Nearest Neighbors (KNN), support vector machines (SVM), and Logistic Regression (LR), and a state-of-the-art deep learning model: LSTM. More specifically, we compare these approaches on two early prediction tasks. Overall, we show that RTPs outperform all baseline models including LSTM on both early prediction tasks and more importantly, RTPs can generate quite reliable predictions with only the first *one* minute data. Additionally, RTPs can discover interpretable, meaningful temporal patterns that would be informative for domain experts or educators.

Our main contributions are summarized as follows: 1) To the best of our knowledge, this is the first attempt to apply RTP mining to extract student programming temporal patterns and compare it with several baseline models, including deep learning. 2) We run extensive experiments evaluating RTP and various baseline models on both the task of early prediction for student success and that of early prediction for student difficulty, while most prior research mainly focused on one or the other but not both. 3) We explored their robustness and the effectiveness of using EF vs. DDF for the programming system on both early prediction tasks. 4) We identify interpretable, meaningful temporal patterns that can be informative for domain experts.

2. BACKGROUND, CONTEXT, & DATA

2.1 Modeling Student Learning

Student modeling has been extensively explored as a series of approaches have been proposed [10, 34, 8, 24] to better understand and model student learning process. Among them, Bayesian Knowledge Tracing (BKT) [10] is one of the most widely investigated student modeling approaches. It models a student’s performance in solving problems related to a given concept using a binary variable (i.e., correct, incorrect) and continually updates its estimation of the student’s learning state for that concept. BKT and BKT-based models have been shown to be effective in many student modeling tasks, such as predicting students’ overall competence [22], predicting the students’ next-step responses [37, 6, 23, 18], and the prediction of post-test scores [16, 19]. However, in this study, BKT-based models cannot be directly applied to our open-ended programming tasks, because of the adversity of mapping students’ time-various actions step by step.

In recent years, extensive research has been conducted on

deep learning models, especially Recurrent Neural Network (RNN) or RNN-based models such as LSTM in the field of educational data mining [25, 33, 15, 35, 36, 17]. In our prior work, we have shown that LSTM has superior performance on the early prediction of student learning gain compared with classic BKT-based models [19]. For the task of predicting students’ responses to exercises, LSTM was shown to outperform conventional BKT [25] and Performance Factors Analysis [24]. However, RNN and LSTM did not always have better performance when the simple, conventional models incorporated other parameters [15, 35].

While most of the previous studies on student modeling focus on predicting students’ success and failure in the next-step attempt, some research has used student-tutor interaction data to predict student post-test scores [11, 30]. In this work, we explore the early prediction of both student success and difficulty. As far as we know, none of the previous studies have explored both prediction tasks for computer-based programming systems.

2.2 Programming and Help-seeking in iSnap

In this work, we analyze data from *iSnap*, a block-based novice programming environment [26]. iSnap is an extension of Snap! [12], which allows students to easily create interactive, 2D applications, such as apps and games. iSnap provides students with on-demand, next-step programming hints, which are generated automatically from student data with the SourceCheck algorithm [28]. In addition, iSnap collects detailed interaction data as students work, including complete snapshots of all student code, allowing us to perform detailed time series analysis. iSnap’s data-driven hints also offer a useful motivation for this work. Prior analysis of student help-seeking behavior in iSnap suggests that few students ask for help when they need it, especially lower-performing students [29]. This is consistent with help avoidance reported in other tutoring systems [2, 4]. Prior works suggest that a number of factors lead to this help avoidance in iSnap, including lack of trust in the system, a desire for independence, and a lack of awareness of their own need for help [27]. Effective help-seeking is a metacognitive skill that many students need additional training to develop [3]. A system that could detect or predict student difficulty times could offer interventions such as automated help or instructor alerts. However, prior work suggests that such proactive intervention is most effective when systems assess the student’s likelihood to succeed [20], rather than responding to all errors with help messages [1]. In this work, we present a data-driven approach capable of making early and accurate predictions of student success, which can enable a variety of interventions, such as iSnap hints.

2.3 Dataset

Our datasets were collected from students using iSnap in an “introduction to computers” course for non-majors, held at a research university, from the Spring 2016 (S16), Fall 2016 (F16), Spring 2017 (S17), and Fall 2017 (F17) semesters. We excluded students who requested hints since hints may alter students’ problem-solving patterns, and our remaining data contained code traces from 65, 38, 29, and 39 students from S16, F16, S17, and F17 respectively. Each *code trace* consisted of a sequence of timestamped *snapshots* of student code. We chose one “Squirrel” assignment to explore

in-depth, where students must write a procedure to draw a spiral with square corners. Common solutions contain 7-10 lines of code and use procedures, loops, variables, and arithmetic operators. In our previous work, we presented a *feature-state* representation that defines a student's state by the presence or absence of specific features of a correct solution [38]. Each feature describes a distinct property of correct solution code and may specify a necessary code structure or required program output. We defined *feature-state* as the presence or absence of each feature in a student's code (e.g. the feature-state "1101000" indicates Features 1, 2 and 4 are complete, while Features 3,5,6, and 7 are missing). In the same work, we implemented an algorithm to identify data-driven code features directly from student solutions, extracting 11 *data-driven features (DDF)*. We also had experts systematically define 7 *expert features (EF)* for the Spiral assignment. Using the expert feature definitions, we manually tagged each student's snapshot and had 6,339 tagged snapshots from 38 traces in F16. Our work showed that the data-driven features and expert features had moderate agreement on whether a student is in the same feature state or different states for F16. Additionally, we implemented an automated expert feature detector to detect the 7 expert features automatically. We used the detector to tag S16, S17, and F17 student snapshots with expert feature-states. On the F16 dataset, the expert feature detector had an agreement of 0.861 with the manually-tagged expert features. In all, we have 31,064 tagged snapshots from 171 traces from S16, F16, S17, and F17 semesters. Finally, we used a smoothing function to the tagged traces in which periods of rapid feature-state changes, defined as transitioning back and forth between two features within a 5 snapshot window, to set the values of a subsequent period after the variance. This process aims to reduce noise generated by actions in Snap! that do not represent meaningful feature-state changes (e.g. a student drags the code to a different position in the environment).

3. TWO EARLY PREDICTION TASKS

In this work, we explore two different early prediction tasks: the trajectory-level early prediction for student success and the event-level early prediction for student difficulty.

3.1 Trajectory-Level: Student Success

We classify the students who finished the programming assignment in one hour or less and got full credit as *successful*, and those who either failed to complete the assignment or submitted it within one hour as *unsuccessful*. Thus, each *trajectory* is assigned one ground truth label based on whether the student finished the assignment successfully or unsuccessfully. As a result, we refer to this task as *trajectory-level* early prediction task for student success. Based on this definition, 59 of 171 students are in the *successful* group, and the remaining 112 are in the *unsuccessful* group.

To predict student success, we are given the first *up to n* minutes of a student's sequence data and our goal is to predict whether the student will successfully complete the programming assignment at any given point in the remaining of the sequence. To conduct this task, we left-aligned all the students' trajectories by their starting times and our *observation window* (the part of data used to train and test different machine learning models) includes the sequences from

the very beginning to the first *n* minutes. If a student's trajectory is less than *n* minutes, our observation window will include his/her entire sequence *except* the last one.

3.2 Event-Level: Student Difficulty

We define that a student is experiencing some sort of difficulty if at *any given moment*, a student fails to make any progress on his/her incomplete or imperfect answer in *the next five minutes*. Failure to make any progress in five minutes (on a supposed-to-be 20-minute programming task) reflects that the student may be experiencing some difficulty. Identifying the moment that a student is experiencing difficulty would allow us to determine when a system could intervene to address difficulty or prevent eventual dropout.

Because we predict whether a student is experiencing difficulty *moment by moment*, we refer to this early prediction task as *event-level* early prediction. More specifically, for a given moment, *n* minutes after starting time, we classify the students who failed to make any progress in the next five minutes as the *intervention* group, and those who made some progress as the *non-intervention* group. Note that we are not considering students who have already completed the training in *n* minutes and they are not assigned to either group. In short, for the event-level early prediction for student difficulty, our observation window contains the first *up to n* minutes of a student's sequence data and our goal is to predict whether the student will experience any difficulty and need intervention in the *next five minutes*.

4. RTP MINING

Our dataset can be represented as a set of trajectories, $X = \{x_1, x_2, \dots, x_N\}$ where $N = 171$ is the total number of trajectories, one per student. It is composed of multivariate irregular time series data in that a student i 's trajectory x_i consists of a sequence of events: $x_i = \{x_i^1, \dots, x_i^{T_i}\}$, where x_i^t represents the student's code-records at time step t . We have $x_i^t \in \mathbb{R}^D$, where D is the number of predefined attributes/features and each attribute is a binary variable indicating whether a feature is present or not: $\mathbb{R} \in \{0, 1\}$. T_i is the length of the trajectory x_i ; for different students, T_i varies. Each x_i is associated with a trajectory-level label (e.g. student success) or a series of moment by moment event-level labels (e.g. student difficulty), denoted as $Y = \{y_1, y_2, \dots, y_{T_i}\}$, where $y_i \in \{0, 1\}$. It is important to note that in the trajectory-level student success prediction, we treat students who are unsuccessful as the task of interest; thus, they are assigned to be 1 because it is more important for our model to classify and recognize the unsuccessful students as soon as possible. Similarly, for the event-level student difficulty task, we treat students who need intervention as the task of interest, and thus are assigned as 1.

Generally speaking, our RTP mining is conducted by following four steps: 1) Convert binary time-series variables into time interval sequences using Knowledge-based Temporal Abstraction, as described in the next section. 2) Extract frequent recent temporal patterns from different classes of data (i.e. 0 and 1). 3) Transform each x_i into a fixed-size binary feature vector v_i , where the size of vector corresponds to the number of frequent RTPs from Step 2. 4) Build the model on the binary matrix generated in Step 3 to predict the outcomes.

Figure 1: An example of conversion from the original data into a Multivariate State Sequence with three temporal features.

Typically, temporal abstraction involves defining 1) discretized data, 2) multivariate state sequences, 3) temporal relations, and 4) temporal patterns [32]. Our binary data are already discretized, so we describe the remaining three steps.

4.1 Knowledge-based Temporal Abstraction

Multivariate State Sequences: The middle table in Fig. 1 demonstrates how binary data can be converted into Multivariate State Sequences (MSS), z_i where each row presents a state interval, E , extracted from the student's trajectory. We denote a **State** S as (F, V) , where F is a temporal feature and V is the value for feature F at a given time and the **State Interval** E is denoted as (F, V, s, e) , where s and e refer to the *start* and *end* times of the state (F, V) . Thus, we can convert each student's data x_i into a corresponding MSS z_i by sorting all the state intervals by their start times:

$$z_i = \langle E_1, E_2, \dots, E_n \rangle : E_j.s \leq E_{j+1}.s, j \in \{1, \dots, n-1\}$$

Note that we also define $z_i.end$ as the end of the last state interval in the MSS, i.e. $E_n.e$. For example, the right figure of Fig. 1 is a visualization of the MSS z_i , and $z_i.end$ is 241. Applying this method on all $x_i \in X$ transforms X into a set of MSSs: $Z = \{z_1, z_2, \dots, z_N\}$.

Figure 3: A temporal pattern P with 5 states $\langle S_1 = (F1, 0), S_2 = (F2, 0), S_3 = (F3, 0), S_4 = (F4, 1), S_5 = (F2, 1) \rangle$ and temporal relations presented by half matrix R

Fig. 2. Thus, the two temporal relations, before (b) and co-occurs (c), between two instantaneous events E_i and E_j , are defined as :

- E_i **before** (b) E_j : When E_i ends before the start of E_j ($E_i.e < E_j.s$).
- E_i **co-occurs** (c) with E_j : When E_i and E_j have some overlap ($E_i.s \leq E_j.s \leq E_i.e$).

Figure 2: Allen's 7 basic temporal relations, grouped as before, or co-occurs.

Temporal Relations: We define two temporal relations, based on Allen's 7 basic temporal relations between states[5], grouping the last six into one *co-occurs* relation as shown in

Temporal Patterns: Temporal patterns are generated by combining states and temporal relations (before (b) and co-occurs (c)) to describe temporal dependencies in data. More specifically, for n states $\langle S_1, \dots, S_n \rangle$, we define the corresponding temporal pattern: $P = (\langle S_1, \dots, S_n \rangle, R)$, where R is an upper triangular matrix of relations, with $R_{i,j} \in b, c$ corresponding to the relation between S_i and S_j . The size of temporal pattern P is determined by the number of states S it contains. For example, a 5-pattern with three temporal features is shown in Fig. 3, where each state is an abstraction of a variable and the half matrix on the right shows the temporal relations between each pair of states. For example, since $S2 = (\text{Feature 2}, 0)$ happens before $S4 = (\text{Feature 2}, 0)$, $R_{2,4} = b$. In the next step, we describe a method to find the recent temporal patterns (RTPs) from MSSs in Z .

RTP Mining: We selected the RTP mining algorithm proposed by Batal et al. [7], because it incorporates a maximum gap parameter to consider the recency of patterns, it is efficient, and it prevents incoherent patterns. Next, we define

Figure 4: An example of generating 3-patterns out of a single 2-RTP, by appending a new state.

Recent Temporal Patterns (RTP) and briefly explain how they are applied in our work.

Recent Temporal Patterns: First, we call state interval $E = (F, V, s, e)$ a *Recent State Interval* of MSS z_i if: 1) E is the last state interval for feature F ; that is, for all $E' = (F, V', s', e')$, we have $E'.e \leq E.e$; or 2) E is less than g time units away from the end time of the last state interval: $z_i.end$; that is, $z_i.end - E.e \leq g$.

Given an MSS z_i , a temporal pattern $P = (\langle S_1, \dots, S_n \rangle, R)$, and a maximum gap parameter g , we say P is a recent temporal pattern (RTP) in z_i , denoted as $R_g(P, z_i)$, if all 3 of the following conditions hold: 1) z_i contains P , where $P \in z_i$ if: (a) z_i contains all k states of P , and (b) all temporal relations of P are satisfied in z_i ; 2) $S_n = (F_n, V_n)$ matches a recent state interval in z_i ; and 3) Every consecutive pair of states in P maps to a state interval less than g time units apart. That is, each pair of temporal sequences should not be g time units apart. In short, parameter g forces patterns to be close to the end of the sequence z_i , and forces consecutive states to be close to each other.

Mining Algorithm: For each MSS z_i , its outcome $y_i = 1$ when the z_i sequence is unsuccessful/needs intervention, and $y_i = 0$ otherwise. Taking student success classification as an example, we will have two sets of labeled MSSs: $Z_1 = \{z_i : y_i = 1\}$ for all unsuccessful sequences and $Z_0 = \{z_j : y_j = 0\}$ for all successful ones. Given Z_1 , the mining algorithm applies a level-wise search to find frequent RTPs. More specifically, it first starts with all frequent 1-RTPs, and then extends the patterns by adding a new state to each sequence, one at a time, until no new patterns are discovered. That is, at each level k , the algorithm finds frequent $(k+1)$ -RTPs by repeatedly extending k -RTPs through Backward candidate generation, and the Counting phase, as described below.

Backward $(k+1)$ -pattern candidates are generated from a k -pattern $P = (\langle S_1, \dots, S_k \rangle, R)$, by adding a new frequent state, S_{new} , to the beginning of the sequence to create $P' = (\langle S_{new}, S_1, \dots, S_k \rangle, R')$. Then we specify the new before (b) or co-occurs (c) relations R' between S_{new} and all original k states, restricted by the following two criteria: 1) Two state intervals of the same temporal feature cannot co-occur. That is, if $S_{new}.F = S_i.F$ for $i \in \{1, \dots, k\}$, then $R'_{new,i} \neq c$. 2) Since the state sequence in pattern P is sorted by the start time of the states, once a relation becomes *before*: $R'_{new,i} = b$ for any $i \in \{1, \dots, k\}$, all the following relations have to be *before*, so $R'_{new,j} = b$ for $j \in \{i+1, \dots, k\}$.

In the Counting phase, candidate $(k+1)$ -patterns are removed if they do not meet the minimum support threshold by occurring at least σ times as RTP in Z_1 . The same procedure is carried out for Z_0 . Finally, we combine all the frequent RTPs into a final Ω set of RTPs.

Binary Matrix Transformation: We transform each MSS $z_i \in Z$ into a binary vector v_i of size $|\Omega|$, such that each 0 and 1 indicates whether the pattern $P_j \in \Omega$ is a recent temporal pattern in Z_i or not. This will result in a binary matrix of size $N \times |\Omega|$, which represents our original dataset.

Learning Models: Once the binary matrix is built, we apply different machine learning models including KNN, logistic regression (LR), and SVM to perform each target task.

5. EXPERIMENTS

5.1 Seven models in Three Categories

To evaluate the RTP-based models for early prediction of student success and student difficulty, we conducted a series of experiments. For each task, we used grid search to investigate the optimum value for the maximum gap (g) and minimum support (σ) parameters and we have $g = 60$ minutes and $\sigma_0 = 0.2$ for both prediction tasks. For each task, we compared RTP against two categories of baselines: the three *Classic ML models* and *LSTM*. Thus in total, we explored seven classification models in three categories.

Three Classic Machine Learning Models: We explore three classic machine learning models: KNN, LR, and SVM. Since these models do not handle sequence data directly, we used a “Last Value” approach to treat the last measurement of each attribute within the given observation window as the input to train models. Note that “Last Value” approach is also the baseline approach in [7] and many student modeling research. For early prediction settings, we truncated all the sequences in the training dataset in the same fashion as the testing dataset and then applied the Last Value approach on the truncated training dataset. For example, when our observation window is 1 minute, we apply the last value before 1 minute for each sequence and treat them as inputs for each model. For each of the three models, we explored different parameters to obtain the best results, in that, for KNN, we have $k = 10$, for LR we used $L1$ regularization, and for SVM we used *linear* kernel.

One Deep Learning Model: LSTM LSTM is a variation of Recurrent Neural Networks (RNNs) that prevents the vanishing gradient problem among other forms of RNNs [13]. LSTM has a chain-like structure, which enables information to flow among different blocks at different time points. Each block of the LSTM consists of a memory cell state and three gates: Forget, Input, and Output. These three gates interact with each other to control the flow of information. More specifically, the Forget gate determines what information from the previous memory cell state is expired and should be removed; the Input gate selects information from the candidate memory cell state for updating; the Output gate filters the information from the memory cell so that the model only considers information relevant to the prediction task. Therefore, the memory cell plays a crucial role in memorizing previous experiences. In our task, the input is a multivariate temporal sequence from student

work, and the output from the last step is used to make a prediction. We implemented LSTM in Keras with Tensorflow as the back-end engine, and we used one hidden layer with 100 hidden neurons and set the maximum length to accommodate the longest sequence in our data. Typically for LSTM, the whole multivariate time series from student sequence data is used as input data. However, for early prediction, only those events happening within our observation window from each sequence were used. We applied 5-fold cross-validation in order to tune the parameters of the model, including the optimizer, initializer, number of epochs, and number of batches.

Three RTP-based Models: The RTP-based models would first generate the binary matrix through RTP mining and then applied the classical machine learning models, KNN, LR, and SVM, (the same parameter settings as used in classic machine learning models described above) and thus, they are referred as RTP_KNN, RTP_LR, and RTP_SVM, respectively. Prior research on RTPs for prediction have all used entire sequences to extract meaningful temporal patterns. In this work, we explored the effectiveness of RTP for early prediction, by applying the *truncated* training sequences included in observation window to find RTPs. For example, when our observation window is 1 minute, only the first 1 minute of sequences were used for pattern extraction.

5.2 Evaluation Metrics

We evaluated our models using Accuracy, and Recall, F1 Score, and AUC (Area Under ROC curve). Accuracy represents the proportion of students whose labels were correctly identified. Recall tells us what proportion of students who will actually be unsuccessful (or need intervention) were correctly recognized by the model. F1 Score is the harmonic mean of Precision and Recall that sets their trade-off. AUC measures the ability of models to discriminate groups with different labels. Given the nature of the tasks, we mainly use Accuracy and AUC to compare different models. All models were evaluated using 5-fold cross validation.

6. RESULTS

We present our results in three parts. First, we compare the effectiveness of the three categories of models on trajectory-level early prediction of student success. Second, we explore their performance on event-level early prediction of student difficulty. Finally, we discuss the extracted interpretable and meaningful temporal patterns discovered by RTP mining. For both early prediction tasks, we analyze two feature sets: *expert-based features (EF)* and *data-drive features (DDF)*.

6.1 Trajectory-Level: Student Success

[**Observation Window = 1 min**] Table 1 shows the performance of all models using the first-1-minute training sequences to predict students' success. The first row is the baseline model using simple Majority vote; note that we ignored the Recall and F1-measure of the simple Majority baseline. For the three main categories of models, we reported their performance on both EF and DDF. For Classic ML, KNN with DDF generates the highest scores on Recall (0.955) and F1-measure (0.793), SVM with DDF has the best AUC (0.563), and LR with EF contributes the best Accuracy (0.678). Thus, there is no clear winner among the

Table 1: Student success classification performance for the *one-minute* observation window

Model	Feature	Accuracy	Recall	F1	AUC
Majority Baseline	EF/DDF	0.655	-	-	0.5
Classic ML	KNN	EF	0.667	0.946	0.788
		DDF	0.673	0.955	0.793
	SVM	EF	0.661	0.946	0.785
		DDF	0.673	0.920	0.786
	LR	EF	0.678	0.938	0.792
		DDF	0.520	0.464	0.559
Deep Learning	LSTM	EF	0.649	0.991**	0.787
		DDF	0.655	0.991**	0.790
RTP	RTP_KNN	EF	0.965	0.973	0.973
		DDF	0.906	0.902	0.927
	RTP_SVM	EF	0.971**	0.955	0.977
		DDF	0.965	0.955	0.973
	RTP_LR	EF	0.971**	0.973	0.978**
		DDF	0.959	0.964	0.969

Note: best model for each group in **bold**, overall best model marked **

three models here. Between the two types of features, it seems that DDF is slightly better or as good as EF for KNN and SVM, but much worse than EF for LR. Between the two LSTM models, LSTM with DDF works better than LSTM with EF. For RTP-based models, the best Accuracy (0.971) is from RTP_SVM and RTP_LR and both with EF, the best Recall (0.973) is generated by RTP_KNN and RTP_LR and both with EF, the best F1-measure (0.978) comes from RTP_LR with EF again, and the best AUC (0.978) is generated by RTP_SVM with EF. So for RTP-based models, EF generally works better than DDF. However, for RTP_LR and RTP_SVM, the performance of the EF and DDF are very close and competitive.

Finally, across the three categories, RTP-based models have the highest score on every measure except that LSTM has the highest Recall. While all the highest measurements come from using EF, the performance of DDF is very close to EF especially when using LSTM, RTP_LR and RTP_SVM. More importantly, the performance of all the RTP-based models are very high, above 95% on every measure.

[**Observation Window = 1 ~ 20 mins**] Fig. 5 and Fig. 6 report Accuracy and AUC performance for all models using EF and DDF respectively. For each graph, we vary the observation window from the first 1 minute up to the first 20 minutes. Both Fig. 5 and Fig. 6 show that RTP_LR and RTP_SVM were the best models for both using EF and DDF as they stay on the top across all sizes of the observation window. It is not surprising that for the three classic models and LSTM, the longer the observation windows, the better performance they achieve. This is because the training data includes more and more information and closer to their final state. For RTP_KNN, both EF and DDF first decrease dramatically from 1 to 5 minutes and then increase slightly but still, the best performance comes from using only the first *one* minute. For RTP_LR and RTP_SVM, their performances are not only the best but also very steady. The fact that the best prediction comes from using just the first *one* minute of the sequences and using RTP-based models really suggest that *how* students try to solve the problem, what actions they take and in what order in that minute really matters for determining their final success. However, this is only observation from one programming task and more research is needed for further investigation.

(a) Accuracy performance

(b) Area under ROC performance

Figure 5: Student success early prediction on *expert* feature set

When comparing using EF and DDF, Fig. 5 and Fig. 6 shows that the general patterns of performance of different machine learning models are very similar between using EF and DDF with a few exceptions. In general, using EF seems working better than using DDF and the exceptions are: for RTP_LR, and RTP_SVM, the best two models, the performance of using EF and using DDF are very close and sometimes using DDF is even better than using EF.

6.2 Event-Level: Student Difficulty

Table 2: Student difficulty classification performance for *one-minute* observation window

Model	Feature	Accuracy	Recall	F1	AUC
Majority Baseline		0.753	-	-	0.5
Classic ML	KNN EF	0.806	0.238	0.377	0.615
	KNN DDF	0.800	0.214	0.346	0.603
	SVM EF	0.806	0.214	0.353	0.607
	SVM DDF	0.800	0.238	0.370	0.611
	LR EF	0.765	0.238	0.333	0.588
	LR DDF	0.771	0.238	0.339	0.592
Deep Learning	LSTM EF	0.753	0.224	0.344	0.596
	LSTM DDF	0.871	0.269	0.389	0.624
RTP	RTP_KNN EF	0.994**	1**	0.988**	0.996**
	RTP_KNN DDF	0.971	0.976	0.943	0.972
	RTP_SVM EF	0.988	0.976	0.976	0.984
	RTP_SVM DDF	0.971	0.952	0.941	0.964
	RTP_LR EF	0.994**	1**	0.988**	0.996**
	RTP_LR DDF	0.988	1**	0.976	0.992

Note: best model for each group in **bold**, overall best model marked **

[Observation Window = 1 min] Table 2 shows the performance of all models using the first-1-minute-training sequences to predict students' difficulty in the next five min-

(a) Accuracy performance

(b) Area under ROC performance

Figure 6: Student success early prediction on *data-driven* feature set

utes. As with Table 1, it is not very meaningful to present the Recall and F1-measure of the simple Majority baseline (row 1). For Classic ML models, KNN using EF generates the highest scores on every measure but not much better than the other two. In fact, all three models perform very closely regardless of using EF or DDF, and they all performed pretty poorly in that their performances on recall, F1 and AUC are all below 62%. Again for this task, the LSTM models outperform the classic models but not by much. Although LSTM with DDF works better than EF, the resulted models are still not very effective. Finally, for RTP-based models, RTP_KNN and RTP_LR reach the highest scores on every measure. Both of them have the best Accuracy (0.994), the best Recall (1), the best F1-measure (0.988), and the best AUC (0.996). RTP_SVM can make comparable predictions with over 97% on every measure.

In general, the best model among all the seven models uses RTP, which has the highest score on every measure. Comparing the models on different feature sets, we can find that the models with DDF are able to generate very similar results as those with EF. And sometimes, models with DDF had better performance on the first 1 minute, such as LR and LSTM.

[Observation Window = 1 ~ 20 mins] Fig. 7 and Fig. 8 show the results from EF and DDF respectively. We mainly reported the performance of Accuracy and AUC on the observation sets {1m, 5m, 10m, 15m, 20m}. Note that different from trajectory-level early prediction, our majority baseline for event-level early prediction on student difficulty is changing moment by moment and for an observation window n ,

Figure 7: Student difficulty early prediction on *expert* feature set

all the students whose trajectories are shorter than n are excluded from the evaluation. So we have different baseline majority accuracy for different observation window (shown in black bar). For AUC, majority vote would give us a baseline of 0.5. Both Fig. 7 and Fig. 8 show that RTP_LR is the best one among all the models no matter which feature sets were used, with the highest scores on both Accuracy and AUC for all observation windows. Additionally, when comparing RTP_LR with EF and RTP_LR with DDF, we can see that RTP_LR with DDF generally perform much better than RTP_LR with EF. By comparing the results from Fig. 7 and Fig. 8, RTP_LR and RTP_SVM really benefit from using DDF instead of EF in that while RTP_LR and RTP_SVM with DDF perform very closely with RTP_LR and RTP_SVM with EF when the observation window = 1m, the RTP_LR and RTP_SVM with DDF performed much better and more stable than RTP_LR and RTP_SVM with EF on all the following observation windows and the difference are large. For the rest of machine learning models, the difference between using DDF and using EF is not noticeable. Finally, note that Fig. 7 shows when the observation window = 5m, the best performance using EF is 65% accuracy and < 70% of AUC achieved through RTP_LR ($x - axis = 5m$); however, when we use the same observation window, RTP_LR with DDF can achieve the accuracy close to 95% and AUC above 90% (shown in Fig. 8). So overall, for the task of event level early prediction for student difficulty, RTP_LR with DDF consistently achieve the best performance and its performance is pretty steady across different observation windows.

6.3 Knowledge Discovery

One substantial advantage of pattern-based classification over deep learning models is the *interpretability* of the discovered

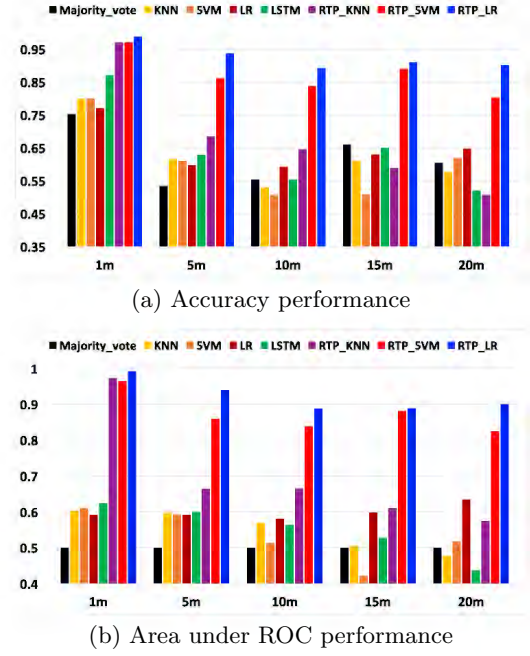

Figure 8: Student difficulty early prediction for *data-driven* feature set

patterns. In RTP, the patterns need to be representative of the original time series data while predictive of the future outcomes. In this study, most of the patterns extracted using RTP mining are in accordance with the student classification tasks and some of them reveal latent patterns towards the progression of student success or difficulty. Table 3 and 4 present a number of interesting patterns and their corresponding support among the training group from the first 20 minutes, where the support of pattern P is calculated as the proportion of students in the dataset which contains P .

Table 3 shows some patterns related to student success. $P_1 - P_4$ describe the frequent patterns found among unsuccessful students, and most of them are related to the feature *MoveVariably*. P_1 , P_2 and P_3 illustrate that students did not complete feature *CreateUseParameterCorrectly*, *RepeatCorrectNumberOfTimes*, or *MoveSquirally* when feature *MoveVariably* has been completed. In P_1 , students may start to work on *DrawAnything* and *MoveSquarelikeThing*, which is observable among 29.5% of unsuccessful students from their sequences in the first 20 minutes. Different from P_1 , students with pattern P_2 and P_3 were probably working on *CustomBlock* before they finished feature *MoveSquirally*. P_4 indicates that students had finished features *MoveVariably* and *MoveSquarelikeThing* but failed at the end, which might be the case that they had done some movements but did not have pen down. And still, neither *CreateUseParameterCorrectly* nor *RepeatCorrectNumberOfTimes* was finished. $P_5 - P_8$ describes the frequent patterns found among successful students, and most of them are related to the feature *RepeatCorrectNumberOfTimes*. For example, P_5 shows that students had finished feature *CustomBlock*, *CreateUseParameterCorrectly* and *RepeatCorrectNumberOfTimes* at some point, and before that, within 20 minutes, they should be working

Table 3: Recent temporal patterns for student success, with observation window = 20m

RTP	If	Then	Support
P_1	(CreateUseParameterCorrectly,0) c (((DrawAnything,0) c (MoveSquarelikeThing,0)) b (MoveVariably,1))	Unsuccessful	0.295
P_2	((CustomBlock,0) b (MoveVariably,1)) c (CreateUseParameterCorrectly,0) c (RepeatCorrectNumberOfTimes,0)	Unsuccessful	0.286
P_3	((CustomBlock,0) b (CreateUseParameterCorrectly,0)) c (RepeatCorrectNumberOfTimes,0) c (MoveSquirally,0) c (MoveVariably,1)	Unsuccessful	0.233
P_4	((DrawAnything,0) b ((MoveSquarelikeThing,1) c (MoveVariably,1))) c (CreateUseParameterCorrectly,0) c (RepeatCorrectNumberOfTimes,0)	Unsuccessful	0.205
P_5	(CustomBlock,0) b (CustomBlock,1) c (CreateUseParameterCorrectly,1) c (RepeatCorrectNumberOfTimes,1)	Successful	0.729
P_6	(CustomBlock,0) c (MoveSquarelikeThing,0) b (MoveSquarelikeThing,1) c (RepeatCorrectNumberOfTimes,1)	Successful	0.542
P_7	(DrawAnything,0) b (CreateUseParameterCorrectly,0) b (CreateUseParameterCorrectly,1) c (MoveVariably,1)	Successful	0.423

Table 4: Recent temporal patterns for student difficulty, with observation window = 20m

RTP	If	Then	Support
P_1	((((DrawAnything,0) c (MoveSquarelikeThing,0)) b (CustomBlock,1)) c (RepeatCorrectNumberOfTimes,0) c (MoveSquirally,0))	Intervention	0.372
P_2	((((CustomBlock,0) c (DrawAnything,0)) b ((CustomBlock,1) c (MoveVariably,1))) c (MoveSquirally,0))	Intervention	0.302
P_3	((DrawAnything,0) c (MoveSquarelikeThing,0)) b ((CustomBlock,1) c (DrawAnything,1)) c (MoveSquirally,0)	Intervention	0.279
P_4	((MoveSquarelikeThing,0) b ((MoveSquarelikeThing,1) c (MoveSquirally,1))) c (RepeatCorrectNumberOfTimes,0)	Non-intervention	0.461
P_5	((((DrawAnything,0) c (MoveSquarelikeThing,0)) b (MoveSquirally,1)) c (RepeatCorrectNumberOfTimes,0))	Non-intervention	0.422
P_6	(DrawAnything,0) c (MoveSquarelikeThing,0) c (CreateUseParameterCorrectly,0) c (RepeatCorrectNumberOfTimes,0) c (CustomBlock,1)	Non-intervention	0.320

on *CustomBlock*. Actually, for the students in successfully group, they should be able to finish all the features in one hour. Glancing over the extracted patterns among the successful group, we can see that most of the students ended up completing at least two important features, like patterns P_6 and P_7 in the Table 3, in the first 20 minutes. It is important to note that these patterns are only discovered among the successful group.

Table 4 shows some patterns related to student difficulty. $P_1 - P_3$ describe the frequent patterns found among the intervention group, and most of them are related to the feature *CustomBlock*. P_1 describes a pattern that discovered among 37.2% of students who need intervention in the next five minutes. In this case, students had not completed the *DrawAnything* or *MoveSquarelikeThing* features at first, but, within 20 minutes, they completed the *CustomBlock* feature. And at the same time, they did not complete feature *RepeatCorrectNumberOfTimes* or *MoveSquirally*. P_2 and P_3 are quite similar, they indicate that students finished *CustomBlock* along with *DrawAnything* or *MoveVariably* when the feature *MoveSquirally* had not been finished. P_4 to P_6 describe the frequent patterns found among students who do not need intervention, and most of them are related to the feature *MoveSquirally*. $P_4 - P_5$ show that students successfully completed feature *MoveSquirally* and before that, they may work on *MoveSquarelikeThing*. As in P_1 , they have ‘0’ on the feature *RepeatCorrectNumberOfTimes*. Comparing P_1 with P_5 , we can find that instead of having incomplete *DrawAnything* and *MoveSquarelikeThing* before completing *CustomBlock*, students who have incomplete *DrawAnything*, incomplete *MoveSquarelikeThing*, and complete *CustomBlock* at the same time will not need intervention in the next five minutes. Again, these patterns are uniquely inferred among the non-intervention group.

7. CONCLUSIONS

Early prediction of trajectory-level student success and the event-level difficulty during long-term activities are challenging tasks due to the open-ended nature of programming tasks. In this study, we explored the EF identified by domain experts, as well as DDF identified automatically, to build a model that is able to predict student success/difficulty with

high accuracy, and to provide valuable insights for educators. We employed an RTP-based classification framework and compared it with various baselines including classic and deep learning models, in two different tasks including trajectory-level early diagnosis and event-level early prediction. Our results suggest that the RTP-based models consistently outperform the non-temporal classic baselines as well as LSTM in both tasks, at all observation windows from first 1 minute to 20 minutes. Moreover, with only the first-1-minute sequences, RTP-based models can make strong predictions on both tasks. Additionally, by applying the data-driven features, RTP-based models are able to achieve comparable performance on the task of predicting student success. For the task of predicting event-level student difficulty, data-driven features can even improve their predictions further.

As future work, we plan to apply progressive features with multiple values (eg. not started, in progress, complete) to discover more definitive patterns and obtain more advantageous knowledge discovery as well as improved prediction performance. And we are planning to employ different feature transformations other than binary, such as vertical support (i.e. the number of times a pattern occurred in a sequence) or recency measure (i.e. how distant a pattern occurred from the prediction time). Also, this work will be applied to larger groups of students and longer programming tasks, along with integration of more informative features such as intervention and demographic features to develop more robust models. Additionally, we plan to expand our evaluations to longer programs with more complex constructs from both text-based and block-based programming languages.

ABSTRACT

Sequencing items in adaptive learning systems typically relies on a large pool of interactive question items that are analyzed into a hierarchy of skills, also known as Knowledge Components (KCs). Educational data mining techniques can be used to analyze students response data in order to optimize the mapping of items to KCs, with similarity-based clustering as one of the two main approaches for this type of analysis. However, current similarity-based methods make the implicit assumption that students' performance on items that belong to the same KC should be similar. This assumption holds if the latent trait (mastery of the underlying skill) is relatively fixed during students' activity, as in the context of *testing*, which is the primary context in which these methods were developed and applied. However, in adaptive learning systems that aim for *learning*, and address subject matters such as K-6 Math that consist of multiple sub-skills, this assumption *does not* hold. In this paper we propose a new item-similarity measure, termed *Kappa Learning* (KL), which aims to address this gap. KL identifies similarity between items under the assumption of *learning*, namely, that learners' mastery of the underlying skills changes as they progress through the items. We evaluate KL on data from a K-6 Math Intelligent Tutoring System, with experts' tagging as ground truth, and on simulated data. Our results show that clustering that is based on KL outperforms clustering that is based on commonly used similarity measures (Cohen's Kappa, Yule, and Pearson), and that KL is also superior in the task of discovering the number of KCs.

Intelligent Tutoring Systems, Adaptive Learning, Clustering Educational Items, Similarity Measurement

1. INTRODUCTION

Mastery learning [4] is based on the assumption that the domain knowledge can be analyzed into a hierarchy of component skills, with prerequisites between them [9, 10]. This

structure can be used to sequence learning in an Intelligent Tutoring System (ITS) so that students master prerequisite skills before moving to skills that depend upon them [10]. *Cognitive model* is a formal representation of this structure that is encoded into the ITS. It is typically generated in a process that relies on domain experts, learning scientists, and programmers [6].

A significant part of this process is the mapping of question items into the skills that underlie them (skills are also referred to as Knowledge Components, abbreviated KCs¹; in this paper we use the two terms interchangeably). Q-matrix is a standard representation used in Psychometrics to specify the relationships between individual test items and target skills [28]. Generating item-to-skill mapping requires a significant human-labor and expertise [13]. In addition, evidence shows that experts' mapping of items into skills can be significantly inconsistent with students' learning process [20]. Thus, methods that identify the skills underlying each item, or assist human experts in doing so, can optimize the process by increasing its accuracy and reducing human labor [14, 19].

Constructing Q-Matrix from response data is an active research topic. Barnes [3] "mined" students' data to create concept models that can be used to direct learning paths. Examples within the Psychometrics literature include [11, 21, 28]. A Matrix Factorization-based method for Q-matrix construction was proposed in [12], and was later used for enhancing expert-based Q-Matrices [14]. Learning Factor Analysis (LFA) [6] is a combinatorial search algorithm for optimizing the cognitive model while controlling for model complexity. In [22] it was demonstrated that using LFA to refine the human-generated cognitive model of an ITS improves learning gains. Performance Factor Analysis (PFA) [24] reconfigured LFA to enable predictions for individual students with individual skills (LFA assumes all students accumulate learning at the same rate), and also addresses the multiple KCs problem (standard Knowledge Tracing [10] assumes that each item requires one KC; examples of extensions that address multiple skills include [15, 32]). A different approach for 'human-in-the-loop' Student Model Discovery (finding the item-to-skill assignment that best describes students' behavior) was proposed in [27].

In general, there are two approaches for mapping items into

¹in the Psychometrics literature, skills are also referred to as *latent factors* or *constructs*

Tanya Nazaretsky, Sara Hershkovitz and Giora Alexandron "Kappa Learning: A New Item-Similarity Method for Clustering Educational Items from Response Data" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 129 - 138

skills: *Model-based*, and *Similarity-based* [26]. Model-based methods reduce the dimensionality of the problem and try to infer the latent factors (=skills or KCs) that underlie the items. The methods mentioned above fall into this category. Similarity-based methods are based on the assumption that students will tend to have similar performance on items that require the same skill, thus seek to identify the similarity between pairs of items. Examples of methods that are based on item-similarity measures include [2, 26]. The method that we propose in this paper falls into this category as well.

The first phase of item similarity-based methods consists of computing a similarity measure for each pair of items. This measure can be then used to cluster items, which is naturally interpreted as associating the items of a cluster with a single KC. In [26], different measures of item similarity (Pearson, Cohen’s Kappa, Yule, Jaccard, and Sokal) were evaluated on real and simulated data. A different method for identifying the similarity between pairs of items, which is based on Fisher’s Exact Test of independence, was proposed in [2] and was applied to data from an Introductory Physics MOOC. In addition to correct/incorrect information, ‘item-similarity’ can be based also on other behavioral characteristics, such as response-times [5, 26].

The item-similarity methods used in educational data mining for clustering items make the implicit assumption that the latent trait (mastery of the specific skill) is *fixed* during the learning activity that generated the responses (so students’ responses to items that belong to the same KC should be highly correlated). This assumption may be reasonable in the context of *testing* (summative assessment), which is expected to occur *after* the learning process. (In [26], the authors explicitly refer to this shortcoming of the item-similarity measures and mention that by using these methods “we mostly ignore the issue of learning”, p. 17.) However, this assumption *does not* hold in the context of *learning*. In such cases, the correlation between the items might not be a good indication of their similarity (e.g., students will tend to fail on the first items of each KC, and succeed on later ones).

The goal of this research is to address this gap by providing a measure that can capture similarity in the context of *learning*. For that, we propose a new item-similarity measure termed *Kappa Learning* (KL). The main assumption behind KL is that students’ performance on items belonging to the same KC can be increasing, but not decreasing. As we use dichotomous scoring (correct/incorrect on first attempt), we expect that the performance of student s on KC k would take the form of a ‘step’ function, which moves from 0 to 1 when s masters k (*guess* or *slip* may occur, and introduce noise). To quantify that, KL extends the notion of ‘agreement’ in *Cohen’s Kappa* [8].

We first make the assumption that the items are administered to the students in the same order (defined by the instructional designers), but we later explain how our formula naturally generalizes to random or adaptive ordering. We note that we do not assume that all items belonging to the same KC will be presented to students one after the other, or that all the students attempt all the items. On the contrary, we assume that students can skip items, and that

items from different KCs may interleave (as in the data that we analyze), which makes the clustering non-trivial. We then compare a clustering that is based on KL to clustering that is based on the similarity measures evaluated in [26], and show that KL significantly outperforms them (Jaccard and Sokal, which achieved the lowest results in [26], and also on our data, are omitted from the analysis).

The rest of this paper is organized as follows. In Section 2, we present Cohen’s Kappa and our new measure, Kappa Learning. Section 3 describes the clustering method. The details of the empirical setting and the data are provided in Section 4. In Sections 5 and 6 we evaluate the performance of Kappa Learning against standard similarity measures on real and simulated data, respectively. Finally, in Section 7 we discuss the results and suggest directions for future research.

2. COHEN’S KAPPA AND KAPPA LEARNING

2.1 Cohen’s Kappa

Cohen’s Kappa (sometimes abbreviated as Kappa and denoted S_k) is a measure of inter-rater agreement for nominal scales [8].

$$S_k = \frac{P_o - P_e}{1 - P_e} \quad (1)$$

where:

P_o is an *observed* level of agreement

P_e is an *expected* level of agreement

The observed level of agreement is the proportion of the cases the raters agree upon. The expected level of agreement is the proportion of agreement that is expected by chance.

We consider items as raters, learners as subjects to classify, and learners’ responses as classification results. We interpret learner’s correct/incorrect answer to an item (encoded as 1/0) as the rater’s (=item) attempt to identify if the learner has mastered the KC underlying the item. Let us consider a contingency table summarizing learners’ responses to two different items: Q_1 and Q_2 . Assume n learners answered both items. The number of learners in each cell is defined as follows (Table 1):

- a - number of learners answered both Q_1 and Q_2 correctly
- b - number of learners answered Q_1 incorrectly and Q_2 correctly
- c - number of learners answered Q_1 correctly and Q_2 incorrectly
- d - number of learners answered both Q_1 and Q_2 incorrectly
- n - total number of learners ($n = a + b + c + d$)

The number of cases the raters agree upon (the learner gave the same answer to both items) is equivalent to $a + d$. Intuitively, if two different items belong to the same skill, and

Table 1: A contingency table for Q_1 and Q_2 .

	Q_1 correct	Q_1 incorrect	
Q_2 correct	a	b	a + b
Q_2 incorrect	c	d	c + d
	a + c	b + d	n

learner’s mastery of that skill is *fixed* during the learning activity, the learner is expected to answer both items either correctly or incorrectly, depending on whether the skill is mastered or not. So, it follows that:

$$P_o = \frac{a + d}{n}$$

The items are independent in the sense that each item independently ‘rates’ if a learner belongs to a category of learners knowing a particular KC. So we could compute the level of agreement that is expected by chance as a sum of products of marginal probabilities (Table 1).

$$P_e = \frac{(a + b)(a + c) + (b + d)(c + d)}{n^2}$$

By doing substitution of P_o and P_e into Equation 1 and some straightforward simplification we get:

$$S_k = \frac{2(ad - bc)}{(a + b)(b + d) + (a + c)(c + d)}$$

2.2 Kappa Learning: Adjusting Kappa to Accommodate Learning

To accommodate for learning, we give a different interpretation to the notion of ‘agreement’ in Cohen’s Kappa formula, taking into account possible improvement of learner’s skill, or in other words, learning.

We make the following assumptions on the process:

1. The items are presented to the learners in a fixed order².
2. The items belong to k KCs ($k > 1$); Each item belongs to one KC; Items belonging to different KCs may interleave (which makes the clustering non-trivial)
3. Learner’s success on items belonging to the same KC behaves like a ‘step’ function: Before mastering the skill of KC k , the student fails on items of k ; once mastering the skill underlying k , the student succeeds on future items of k (*guess* and *slip* may occur; we assume no ‘forgetting’).

For a pair of items Q_1 , Q_2 , where Q_1 is presented to the learners *before* Q_2 , we define the values in the contingency table (Table 1) as follows:

- a - number of learners who got both items correct, namely mastered the required skills before getting to Q_1 . This is a case of agreement.

²We later explain how this assumption can be removed

- b - number of learners who got the first item incorrect and the second item correct, namely, mastered the required skill after getting to Q_1 , but before getting to Q_2 . **This is a case of agreement, and is where our measure differs from Cohen’s Kappa**
- c - number of learners who got the first item correct and the second item incorrect. This is the only case interpreted as *disagreement*.
- d - number of learners answered both Q_1 and Q_2 incorrectly. This is a case of agreement.
- n - total number of learners ($n = a + b + c + d$)

Based on these, we define P_o and P_e as follows:

$$P_o = \frac{a + b + d}{n}$$

$$P_e = \frac{(a + b)(b + d) + (a + b)(a + c) + (b + d)(c + d)}{n^2}$$

By doing substitution of P_o and P_e into Equation 1 and some straightforward simplification we get:

$$S_{kl} = \frac{(ad - bc)}{(a + c)(c + d)} \quad (2)$$

We call this measure Kappa Learning and denote it S_{kl} . The values of both Kappa and Kappa Learning range between -1 and $+1$, where 0 means independence, and $+1$ means perfect agreement. In Kappa it is achieved when both c and b are equal to 0 . In Kappa Learning, perfect agreement is achieved when c equals 0 .

3. METHOD

3.1 Similarity Measures

To evaluate the performance of Kappa Learning (denoted S_{kl}), we compare it to the following similarity measures:

- S_k : Cohen’s Kappa inter-rater agreement
- S_p : Pearson product-moment correlation coefficient
- S_y : Yule coefficient of association

Cohen’s Kappa (see also in Subsection 2.1) coefficient is defined as:

$$S_k = \frac{2(ad - bc)}{(a + b)(b + d) + (a + c)(c + d)} \quad (3)$$

Pearson product-moment coefficient is a measure of linear correlation between two variables. When applied to dichotomous data, the Pearson correlation coefficient returns the phi (ϕ) coefficient. So, in terms of a , b , c and d (Table 1) the value of S_p is computed as follows:

$$S_p = \frac{(ad - bc)}{\sqrt{(a + c)(a + b)(b + d)(c + d)}} \quad (4)$$

Yule coefficient of association is a measure of colligation between two binary variables and it is commonly used for

analyzing scores in Item Response Theory (IRT). It is the number of pairs in agreement (ad) minus the number in disagreement (cb) over the total number of paired observations and it is defined as:

$$S_y = \frac{(ad - bc)}{(ad + bc)} \quad (5)$$

All three measures range from minus unity to unity, where 1 indicates perfect agreement, -1 indicates perfect disagreement and 0 indicates no relationship [30]. A thorough evaluation of these measures as means for clustering items in an interactive learning environment was done by Řihák and Pelánek [26] (they analyzed the most appropriate measures among the 76 measures analyzed in [7]).

We follow a similar methodology to the one proposed in [26], described below, and demonstrate that Kappa Learning outperforms the other measures.

3.2 Process

Our process has two main steps: 1) Cluster the items based on the four similarity measures (Kappa Learning, and the three reference measures). 2) Compare the goodness-of-fit of the clusterings computed in step 1.

Step 1. Computing the clustering includes the following sub-steps (per similarity measure):

1. From students' performance data, we compute *user-based* item similarity matrix, denoted $M1$. $M1[i, j]$ contains the result of the relevant similarity measure for items q_i and q_j .
2. Compute *item-based* distance matrix from the user-based similarity matrix $M1$. The rationale is that for a pair (q_i, q_j) , if q_i and q_j are similar (i.e., belong to the same KC), they should have a similar distance to a third item q_k (whether it is in the same KC or not). This incorporates more information into the similarity between the items, which should improve the accuracy of the clustering [26]. We denote the *item-based* distance matrix with $M2$. Two standard metrics are used for computing $M2$: Pearson and Euclidean.
3. Two clustering algorithms are applied on $M2$: K-Means and Ward's Hierarchical [17]. The number of clusters is derived from the hierarchal Knowledge Tree defined by content experts (see Subsection 4.2).

Step 2. Per clustering, we use Adjusted Rand Index (ARI) [16, 25] to measure the goodness-of-fit against ground truth – experts' mapping of the items into Knowledge Components.

ARI is a common measure for comparing the similarity between two clusterings. In ARI, a similarity is interpreted as the number of pairs of items on which the clusterings 'agree', adjusted for the amount of agreement 'by chance'.

To be concrete, assume C is a dataset which contains m items, with two clusterings of C into k clusters, denoted C_1 and C_2 . For a pair of items (i_1, i_2) , C_1 and C_2 'agree' on

(i_1, i_2) iff i_1 and i_2 are either assigned to the same cluster, or to different clusters, in both C_1 and C_2 .

To evaluate the level of agreement between C_1 and C_2 , we define a contingency table with the values a , b , c , and d , as follows:

- a - number of pairs (i_1, i_2) where i_1 and i_2 are assigned to the *same* cluster in C_1 and in C_2 . This is a case of agreement.
- b - number of pairs (i_1, i_2) where i_1 and i_2 are assigned to the *same* cluster in C_1 and to *different* clusters in C_2 . This is a case of disagreement.
- c - number of pairs (i_1, i_2) where i_1 and i_2 are assigned to *different* clusters in C_1 and to the *same* cluster in C_2 . This is a case of disagreement.
- d - number of pairs (i_1, i_2) where i_1 and i_2 are assigned to *different* cluster in C_1 and in C_2 . This is a case of agreement.
- n - total number of pairs ($n = a + b + c + d = \frac{m(m-1)}{2}$)

Using this definition of a , b , c , and d , we can construct a contingency table similar to Table 1 for pairs of items, and compute Cohen's Kappa based on this table, which is equivalent to Adjusted Rand Index [31].

4. EMPIRICAL SETTINGS

4.1 The Learning Environment

We use data from an ITS that teaches Fractions for 4th grade. The students progress through the ITS on their own pace, in a linear order defined by the content experts. The subject matter knowledge that the ITS covers is modeled by a Knowledge Graph, which is described in Subsection 4.2 (since it is hierarchical, hereafter we use the term Knowledge Tree).

The content of the ITS includes 550 items, instructional materials such as videos, and on-line labs that students can use to explore the various concepts. These are arranged in 112 learning units. Each of the learning units contains a collection of items and learning materials and is designed to take approximately 5 – 15 minutes.

The course is divided into two parts. Part A contains 57 learning units which include 337 items, and Part B contains 55 learning units which include 213 items. Concepts are first introduced and explained and are later re-visited. This means that items which require a certain skill can appear in different locations.

4.2 Knowledge Tree and Content Mapping

The course was designed according to a Knowledge Tree (KT) that models the hierarchy of skills that students should master (under the root topic "Fractions for 4th grade"). The KT was developed by the content experts who built the course. The first level, termed 'subject', includes 8 topics. Some of these topics have a second level, termed 'sub-subject'. On this level of the tree (sub-subject + subjects

that do not have second level) there are 19 topics. The division of the first two levels is curricular (e.g., ‘adding fractions’ as the first level, with ‘adding fractions with a common denominator’ and ‘adding fractions with a different denominator’ as its children).

In addition to these two levels, there is a third level, termed ‘goals’, which is orthogonal to the classification into subjects and sub-subjects, and refers to the cognitive type of the task (inspired by Bloom’s Taxonomy [1]). Since the ‘goal’ level is orthogonal to the division into subjects/sub-subjects (see Figure 1), it can be interpreted as refining the categories under ‘subject’ (hereafter denoted *first level + goals*), or as refining the ‘sub-subject’ (hereafter denoted *second level + goals*).

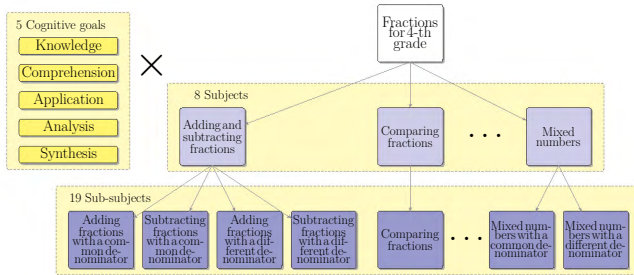

Figure 1: Content expert’s Knowledge tree for the topic “Fractions for 4th grade”. The refining of subjects/sub-subjects into ‘first level + goal’/‘second level + goal’ is computed as a Cartesian product of goals layer with subjects/sub-subjects layers correspondingly.

The experts tagged each item with the ‘subject’, ‘sub-subject’, and ‘goal’ it belongs to. In most cases, each item is mapped into one category on each level. In the few cases where an item was mapped into more than one category, we assume that each unique combination of subjects/sub-subjects is actually a new knowledge component (similar to the rationale of [15]). For example, if item i is marked as belonging to subjects 1 and 2, we create a new artificial subject for this combination of subjects. We removed from the data artificial combinations containing only one item, and the few items (< 5) that belong to these combinations.

4.3 Knowledge Components

We interpret Knowledge Component (KC) as a group of items that deal with the same concept (i.e., require the same skill)³. We examine classifications of items into Knowledge Components that are based on different levels of granularity with respect to the Knowledge Tree. For example, ‘first level’ is a classification that is based only on the first split of the tree (‘subject’). Table 2 presents the number of KCs defined by each level of the KT.

4.4 Data

The data include the responses of 594 4th grade students, who used the ITS for a few hours a week during regular class hours, for a period of 2 months. (We remove the data

³We use the term KC in two ways – as *skill*, and as a *set of items* that require a certain skill

Table 2: Number of Knowledge Components by the level of Knowledge Tree.

Level of Knowledge Tree	Number of Knowledge Components
First	14
First with Goals	42
Second	32
Second with Goals	62

of students who attempted less than 50 items, and the few who had less than 25% success on first attempt, as we assume they were mainly ‘gaming the system’). On average, students spent about 12 hours in the ITS.

Students’ performance is operationalized as *correct on first attempt*. From the log files, we build a 0/1 *student* \times *item* response matrix, denoted RM . $RM[i, j] = 1$ iff students i solved item j correctly on first attempt.

5. RESULTS ON REAL DATA

5.1 Computing the Similarity Matrix

We compute the similarity matrix for each of the four measures, as described in Section 3. This yields four similarity matrices.

To cluster the items based on these matrices, we use three clustering algorithms:

- Ward’s Hierarchical clustering using Pearson correlation Distance
- Ward’s Hierarchical clustering using Euclidean Distance
- K-means clustering using Euclidean Distance

As noted before, the number of clusters is defined according to the number of Knowledge Components of the Knowledge Tree (Table 2). Goodness-of-fit of clustering is evaluated by measuring its similarity to the ground truth labeling, using Adjusted Rand Index (ARI).

5.2 Results of Hierarchical Clustering

Table 3 demonstrates the results of the Hierarchical Clustering on the entire course, based on the four similarity measures, using Pearson Distance (which outperforms Euclidean Distance in all combinations; thus we omit the results for Euclidean Distance). As can be seen, clustering that is based on Kappa Learning outperforms the other measures in all the combinations.

5.3 Results of K-Means Clustering

In addition to the comparison that is based on Hierarchical Clustering, we make a comparison that is based on K-Means Clustering. Since K-Means is non-deterministic (depends on random assignment of initial cluster centers), we run the algorithm 100 times for each combination, each time computing the Adjusted Rand Index against ground truth. The distribution of the Adjusted Rand Index for each combination are presented in Figures 2 and 3. As can be seen, Kappa Learning outperforms the other similarity measures.

Table 3: Adjusted Rand Index for different similarity measures, using Hierarchical Clustering and Pearson Distance, for number of KCs that is based on different levels of the Knowledge Tree.

	First	First with Goals	Second	Second with Goals
Kappa Learning	0.26	0.21	0.26	0.36
Kappa	0.16	0.17	0.18	0.27
Yule	0.15	0.19	0.21	0.29
Pearson	0.16	0.18	0.21	0.30

Figure 2: Results of K-means clustering for the entire course and number of KCs as defined by the second level of the Knowledge Tree. The vertical dashed line goes through the mean of the distribution of the ARI results for Kappa Learning.

Figure 3: Results of K-means clustering for the entire course and number of KCs as defined by the second level of the Knowledge Tree + Goals. The vertical dashed line goes through the mean of the distribution of the ARI results for Kappa Learning.

5.4 Finding optimal number of clusters

While the clustering algorithms described above take the number of clusters as input, in many real-life scenarios it is unknown in advance and needs to be discovered from the data. Finding an optimal number of clusters is a fundamen-

tal problem in clustering analysis that is typically ill-posed [16], as there is no rigorous definition of a cluster, and the practical considerations are domain and application-specific. For example, in our model, we consider number of clusters that is based on different resolution of experts' hierarchical Knowledge Graph (Subsection 4.2).

The 'goodness' of the resulting clustering is usually measured by cluster cohesion and cluster separation. One of the measures for cluster cohesion or compactness is Within Cluster Sum of Squares (WSS), W_k . For any clustering of a set S into k clusters $S = \{S_1, S_2, \dots, S_k\}$, WSS is defined as

$$W_k = \sum_{i=1}^k \frac{1}{2|S_i|} \sum_{x,y \in S_i} [dist(x,y)]^2 \quad (6)$$

where $dist(x,y)$ is a measure for distance between two items of a set.

In our case the value of W_k depends on the method used for evaluating the item's similarity matrix based on student's performance matrix, the method for measuring the distance between items of similarity matrix and the clustering algorithm used. Within Clusters Sum of Squares is commonly used to find an optimal number of clusters using the 'elbow' heuristic, however, in our case, there is no clear 'elbow' in the graph. Another common method for estimating an optimal number of clusters using WSS measure is the Gap statistic method.

5.4.1 Gap Statistic

The main idea of Gap statistic is comparing the goodness of clustering applied to a specific dataset with the goodness of clustering obtained when applied on a uniformly distributed data with no clustering structure at all (so-called 1-cluster data) [29]. The GAP_k measure used in Gap statistic is the difference between an expected value of $\log(W_k)$ computed for clustering of 1-cluster random data into k clusters and $\log(W_k)$ value obtained from clustering of input dataset into the same number of clusters k . The random data is generated from a uniform distribution over the same range as the input dataset. The Gap statistic method receives $K.max$ – the maximal number of clusters to consider, a clustering algorithm, a distance measure, and an input dataset. For each k from 1 to $K.max$, it computes GAP_k value and searches for the value of k that maximizes the Gap value.

For the four similarity matrices obtained (Section 3) we compute Gap statistic using Ward's Hierarchical Clustering, Pearson distance and $K.max = 70$. Then we apply two different methods for computing the optimal number of clusters: First SE Max (first local maximum of Gap value within one standard error) and First Max (first local maximum of Gap value) [29].

Running Gap statistic on Kappa Learning dataset produces 19 as an optimal number of clusters (see Figure 4), which is similar to the number of Knowledge Components at the Second level of the Knowledge Tree (see Figure 1; the second level of the Knowledge Tree is denoted 'sub-subjects').

The optimal number of clusters based on Yule similarity measure is 14 (with First SE Max) or 15 (with First Max),

Figure 4: The values of GAP statistic for k in a range from 1 to 25 computed based on Kappa Learning similarity matrix. The vertical dashed line indicates the optimal number of clusters as predicted by both firstMax and firstSEMax methods.

which is also quite close to the ground truth. For the two other methods (Cohen’s Kappa, Pearson), Gap statistic does not produce meaningful results (Table 4).

Table 4: Optimal number of clusters by GAP statistic.

	First Max Method	First SE Max Method
Kappa Learning	19	19
Kappa	1	1
Yule	15	14
Pearson	1	1

6. SIMULATION STUDY

In addition to evaluating our method on data from a real learning environment (Subsection 4.1), we conduct a simulation study.

6.1 Data Generation

Our simulation model makes the following assumptions:

1. Each item belongs to one of K knowledge components (KCs); the items are uniformly distributed among these KCs. Each KC has an individual difficulty level (drawn from a probability distribution defined below).
2. The order of appearance of KCs is predefined. We assume that the topic is first presented and explained to the learners, so the majority ($\approx 60\%$, chosen empirically based on the data) of the items that belong to it appear one after the other. The rest of the items

that belong to the KC are presented to the learner on a later stage and interleaved between items from other KCs.

3. Students learn as they interact with the items; Learners have individual learning rate (drawn from a probability distribution defined below).

6.1.1 Hidden Markov Model and Bayesian Knowledge Tracing

Bayesian Knowledge Tracing (BKT) [10] is a popular approach to model skill acquisition in ITSs. It models a student knowledge as a latent binary variable of a Hidden Markov Model. Learning is modeled as a transition from ‘not mastered’ to ‘mastered’ state. The standard BKT model uses the same four parameters for all the students and items. Several studies extended the basic BKT model with individualized parameters for student ability and item difficulty (e.g., [18, 23, 33]). We use the model introduced in [33] as the underlying model for the data generation process.

6.1.2 Individualized Bayesian Knowledge Tracing

We apply Individualized BKT approach with parameter splitting [33] to model a learning process. Namely, we construct individual HMM per student and KC. All items of the same KC are assumed to have the same difficulty. The model assumes students learn as they practice more. On each opportunity to solve an item that belongs to a knowledge component, the probability that the student masters the skill underlying the item’s KC increases.

Let us define:

- L - number of learners
- K - number of Knowledge Components
- N - total number items (questions)

For each KC k and each student l we generate the following parameters:

- $P(L_0)$ - the probability that a student initially knows a particular KC. In this model we assume the students have no initial knowledge.
- $P(T)_l^k$ - the probability of learning for student l and skill k .
- $P(S)$ - the probability of slip, meaning making an incorrect attempt when applying a known skill. We assume $P(S) = 0.1$ (not individualized; determined by an educational expert).
- $P(G)$ - the probability of random guess, meaning making a correct attempt when applying an unknown skill. We assume $P(G) = 0.2$ (not individualized; determined by an educational expert).

As proposed in [33], the value of the parameters $P(T)_l^k$ is combined from two components: a per-skill component and a per-student component. So, we generate for each skill and

each student a pair of parameters $(P(T)_l, P(T)^k)$. Each of the above parameters is generated from a uniform distribution $\mathcal{U}(0, 1)$. Then for each student l and KC k the parameters are combined as follows:

$$P(T)_i^k = \sigma(l(P(T)_l) + l(P(T)^k)) \quad (7)$$

where:

$$\sigma(x) = 1/(1 + \exp^{-x}) \quad (8)$$

and

$$l(x) = \log(x/1 - x) \quad (9)$$

Where $\sigma(x)$ and $l(x)$ are the sigmoid and logit functions, respectively.

The performance matrix for each student and knowledge concept is generated using R's HMM package, and the data is combined into a $L \times N$ student's performance matrix. For all Knowledge Components containing more than 6 items, the first 6 items are placed one after another, modeling the introduction of the concept to the learners. The rest of the items are shuffled randomly between future KCs.

6.1.3 Model Parameters

In the experiment reported below the basic setting is 1000 learners, 20 Knowledge Components, 200 items. The parameters are chosen in a way that approximates the multivariate distribution of the real data with respect to the average number of items per Knowledge Component and the mean performance of students, as illustrated in Table 5.

Table 5: Comparison of simulation model to empirical data.

	Average number of Questions per KC	Average performance of Students
Empirical data	≈ 9	67%
Simulation model	10	64%

To evaluate the clustering that is based on each of the four measures, we follow the same process as described in Section 3. Since the results depend on the simulated data, we repeat the process 700 times, each time starting with generating a new performance matrix.

6.2 Results on Simulated Data

The results are presented in Table 6 (right column) and Figure 5. As can be seen, Kappa Learning outperforms all other measures in its ability to reproduce the original clusters. Table 6 also presents the results of each measure on the real data (left column), for reference.

To verify the statistical significance of the results, we conduct a t-test for the results of Kappa Learning vs. the three other measures (Yule, Cohen's Kappa, and Pearson). For all combinations, the p-value is less than 0.01.

7. DISCUSSION

The results show that Kappa Learning - the new similarity measure that we propose, which is based on adjusting

Table 6: Comparison of Adjusted Rand Index values for different similarity measures.

	Real data, Second level with Goals	Simulation Model (averaged over 700 runs)
Kappa Learning	0.36	0.40
Kappa	0.27	0.35
Yule	0.29	0.31
Pearson	0.30	0.37

Figure 5: Distribution of Adjusted Rand Index values for different similarity measures (KL - Kappa Learning, K - Kappa, Y - Yule, P - Pearson). The vertical dashed line goes through the mean of the distribution of ARI values for Kappa Learning.

Cohen's Kappa to 'learning', can improve the clustering of educational items into Knowledge Components, compared to the state-of-the-art (the measures that are reported in [26] as producing the best results). We ascribe this to the fact that Kappa Learning explicitly models similarity under the assumption that students' skill can grow during the activity (= learning), while the conventional measures are based on the assumption that students' skill is fixed.

On real data, with different combinations for the number of clusters (Table 2), the improvement with Hierarchical Clustering was in the range of 10 – 60% (Table 3), comparing to the conventional measures (Kappa, Yule, and Pearson). On simulated data that follow the 'mastery' assumption, and allow items of different Knowledge Components to interleave (which makes the task more difficult; if all the items of a certain KC are presented together, the clustering is almost trivial), the improvement with Hierarchical Clustering was in the range of 10 – 20% (Table 6).

In real-life scenarios, the number of clusters, which the clustering algorithms that we use take as input, is typically unknown, and it is necessary to extract it from the data. On the task of finding an optimal number of clusters, Gap statistic on clustering that is based on Kappa Learning yielded a number of clusters (19) that is similar to the number of clusters in the ground truth (according to the second level of the Knowledge Graph. See Table 2). Among the other measures, Gap statistic on Yule-based clustering also produced results that are reasonably close to the ground truth. For

Kappa and Pearson, Gap statistic did not yield meaningful results.

Overall, Kappa Learning was superior with respect to all the combinations that were evaluated: Various interpretations of the ground truth (deciding on the KCs according to different levels of Knowledge Graph); clustering algorithm – K-Means and Hierarchical Clustering; real and simulated data; and in reproducing the number of clusters with Gap statistic. Thus, we conclude that in the context of learning in structured domains (such as K-6 Math), Kappa Learning provides a significant improvement to the task of clustering that is based on item similarity, compared to conventional item-similarity measures.

7.1 Generalizing to Random Order of Items

In Subsection 2.2, the definition of Kappa Learning was based on the assumption that the items are presented to the learners in a fixed order. We now explain how this assumption can be removed. Let us assume that the items administered to the learners in a random order, meaning that different learners may see the items in a different order. In this case, for each learner and for each pair of items we construct the contingency table (similar to Table 1) by computing the values of a , b , c , d as follows:

- a - number of learners who got both items correct
- b - number of learners who got the first item presented to them (among Q_1 and Q_2) correct, and the second incorrect
- c - number of learners who got the first item presented to them (among Q_1 and Q_2) incorrect, and the second correct
- d - number of learners who got both items incorrect

7.2 Future Work

This work provides a few directions for future research. On the next step, we intend to work with the developers of the ITS on using the results of Kappa Learning to refine and optimize the pedagogic design of the ITS (cognitive modeling, but also questions such as which KCs require more content, are too difficult, too easy, etc.).

Algorithmic directions include studying additional ways to insert the notion of ‘learning’ into existing item-to-skill detection methods, and additional sources of information such as domain experts or analysis of the body of the items (text, images, mathematical symbols, etc.).

In terms of use cases, it would be interesting to evaluate Kappa Learning on data from a variety of learning environments (e.g., MOOCs) and subject matters, and in particular, on domains in which knowledge is less structured (e.g., reading comprehension).

7.3 Summary and Conclusions

This paper presents a new method for measuring the similarity between educational items, termed Kappa Learning. The novelty of this method, compared to previous measures of similarity between educational items, lies in the fact that

it explicitly captures the notion of ‘learning’, namely, change of the latent trait (student’s mastery of the concept). This is done by extending the notion of ‘agreement’ within Cohen’s Kappa basic formula.

Our results show that clustering that is based on Kappa Learning outperforms clustering that is based on conventional methods (Cohen’s Kappa, Yule, Pearson), on real data from K-6 Math ITS that teaches multiple concepts, and on generated data that simulates learning of multiple, interleaved concepts. Thus, we believe that Kappa Learning is more suitable than existing measures for computing similarity between items in the context of learning in structured domains.

ABSTRACT

Knowledge components (KCs) define the underlying skill model of intelligent educational software, and they are critical to understanding and improving the efficacy of learning technology. In this research, we show how learning curve analysis is used to fit a KC model - one that was created after use of the learning technology - which can then be improved by human-centered data science methods. We analyzed data from 417 middle-school students who used a digital learning game to learn decimal numbers and decimal operations. Our initial results showed that problem types (e.g., ordering decimals, adding decimals) capture students' performance better than underlying decimal misconceptions (e.g., longer decimals are larger). Through a process of KC model refinement and domain knowledge interpretation, we were able to identify the difficulties that students faced in learning decimals. Based on this result, we present an instructional redesign proposal for our digital learning game and outline a framework for post-hoc KC modeling in a tutoring system. More generally, the method we used in this work can help guide changes to the type, content and order of problems in educational software.

Keywords

KC Model, Decimal Number, Digital Learning Game

1. INTRODUCTION

In the view of KC modeling, student's knowledge can be treated as a set of inter-related KCs, where each KC is "an acquired unit of cognitive function or structure that can be inferred from performance on a set of related tasks" [22]. A KC-based student model (which we refer to as *KC model*) has been employed in a wide range of learning tasks, such as supporting individualized problem selection [11], choos-

ing examples for analogical comparison [35] and transitioning from worked examples to problem solving [43]. A good KC model is vital to intelligent educational software, particularly in the design of adaptive feedback, assessment of student knowledge and prediction of learning outcomes [24].

A new area in educational technology that could potentially benefit from KC models is digital learning game. While there has been much enthusiasm about the potential of digital games to engage students and enhance learning, few rigorous studies have demonstrated their benefits over more traditional instructional approaches [32, 34]. One possible reason is that most digital learning games have been designed in a one-size-fits-all approach rather than with personalized instruction in mind [9]. Adopting KC modeling techniques could therefore be an important first step in meeting individual students' learning needs and making digital learning games a more effective form of instruction. A critical question in this direction is whether a KC model can be created after the use of the learning technology, in order to better understand the targeted learning domain and to help in improving the technology.

In our study, we explore this question in the context of a game that teaches decimal numbers and decimal operations to middle-school students. We started with an initial KC model based on problem type (e.g., adding decimals, completing sequences of decimals), then used the human-machine discovery method [51] to derive new KCs and formulate the best fitting model. From this improved model, we first discuss findings about students' learning of decimal numbers and propose potential changes to the instructional materials that address a wider range of learning difficulties - a process known as "closing the loop" [24]. Then, we outline a general framework for adding KC models to educational software in a post-hoc manner and discuss its broader implications in digital learning games.

2. BACKGROUND

In this section, we first present background information about two aspects of student modeling that are relevant to our work: (1) KC modeling, a technique that represents students' knowledge as latent variables, and (2) the current state of student modeling in digital learning games. Then,

Huy Nguyen, Yeyu Wang, John Stamper and Bruce McLaren "Using Knowledge Component Modeling to Increase Domain Understanding in a Digital Learning Game" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 139 - 148

we describe the game environment used for data analysis.

2.1 KC Modeling

Traditionally, KC models have been developed by domain experts, using Cognitive Task Analysis methods such as structured interviews, think aloud protocols and rational analysis [45]. These methods result in better instructional design but are also highly subjective and require substantial human effort. To address this shortcoming, a wide range of prior research has focused on creating KC models through data-driven techniques. Some of the earliest work on identifying and improving KC models was done by Corbett and Anderson [11] with the early LISP tutors. In this work, plotting of learning curves showed “blips” or “peaks” in the curves which indicated new KCs that were not accounted for in the initial model. By using a computational model to fit the data in learning curves, [5] showed how Learning Factor Analysis (LFA) could automate the process of identifying additional KCs in educational software. LFA takes as input a space of hypothesized KCs, which can be discovered through visualization and analysis tools [51]. Once there are several human-generated KC models, they can be combined by merging and splitting skills using machine learning techniques that aim to improve the overall fit [23].

It is important to define a good model, but it is not always clear how to do so. Goodness of fit is best measured by cross validation, but this technique is time consuming and computationally expensive for large datasets. Furthermore, there is no consensus on how cross validation should be performed on educational data [50]. Two related and easy-to-compute metrics are the Akaike information criterion (AIC) and Bayesian information criterion (BIC), which address overfit by measuring prediction accuracy while penalizing complexity. In general, a lower AIC/BIC/cross validation score indicates a better model. In case they do not agree, [50] showed that AIC correlates with cross validation better than BIC, through an analysis of 1,943 KC models in DataShop. However, these scores alone do not portray the full picture; as pointed out by [3], many student modeling techniques that aim to predict student learning achieve negligible accuracy gains, “with differences in the thousandths place,” suggesting that they are already close to ceiling performance. In response, [28] brought attention to another important criterion - whether the model is *interpretable* and *actionable*. As the authors argued, even slight improvement can be meaningful if it reveals insights on student learning that generalize to a new context and lead to better, empirically validated instructional designs. For instance, some research has been successful in redesigning tutor units to help students reach mastery more efficiently, based on analysis of previous KC models [24, 27].

Our analysis follows the established process outlined above, in which we started with a basic human-generated KC model, then identified potential improvements using learning curve analysis, and evaluated the new model by AIC, BIC and cross validation. We also derived instructional insights from this model as the first step in closing the loop.

2.2 Student Modeling in Games

As pointed out by [2], knowledge in digital learning games is harder to represent than knowledge in tutoring systems

because the students’ thinking process, as well as learning objectives, may not be as explicit. The popular student modeling techniques for learning games are those that can represent uncertainty, such as Bayesian Networks (BN) [31] and Dynamic Bayesian Networks (DBN) [8]. For instance, in *Use Your Brainz*, by applying BN to each level of the game to estimate the problem-solving skills of learners, researchers were able to validate their measures of stealth assessment [46]. [10] applied DBN in *Prime Climb*, a math game for learning factorization, to build an intelligent pedagogical agent that results in more learning gains for students. Follow-up work by [30] refined and evaluated the existing DBN, yielding substantial improvement in the model’s test performance prediction accuracy, which in turn helps better estimate students’ learning states in future studies. As another example, [42] employed DBN to predict responses on post-test questions in *Crystal Island*, an immersive narrative-based environment for learning microbiology.

Recent research has proposed entirely data-driven methods for discovering KC models in a tutoring system [17, 26]. However, most KC models employed in digital learning games have been generated manually by domain experts. For instance, in *Zombie Division*, the KCs were identified by math teachers as common prime factors such as “divide by two” and “divide by three” [2]. Similarly, the designers of *Crystal Island* labeled the general categories of knowledge involved in problem-solving as *narrative*, *strategic*, *scenario solution* and *content* knowledge [42]. The first attempt to refine a human-generated baseline KC model using data-driven techniques in digital learning games was done by Harpstead and Alevan [18]. Their approach, which was applied to *Beanstalk*, a game that teaches the concept of physical balance, is based on [51]’s human-machine discovery method, which is very similar to ours; however, there are notable differences in the learning environments. In particular, the domain of decimal numbers involves many more rules and operations than *Beanstalk*’s domain of beam balancing; in turn, our digital learning game also incorporates more activities (e.g., placing numbers on a number line, completing sequences, assigning numbers to less-than and greater-than buckets). Therefore, our KC modeling process takes into account not just the instructional materials but also elements of the interface and problem types, which could be more generalizable to other learning environments.

2.3 A Digital Learning Game for Decimals

Decimal Point is a single-player game that helps middle-school students learn about decimal numbers and their operations (e.g., adding, ordering, comparing). The game is based on an amusement park metaphor (Figure 1), where students travel to various areas of the park, each with a different theme (e.g., *Haunted House*, *Sports World*), and play a variety of mini-games within each theme area, each targeting a common decimal misconception: **Megz** (longer decimals are larger), **Segz** (shorter decimals are larger), **Pegz** (the two sides of a decimal number are separate and independent) and **Negz** (decimals smaller than 1 are treated as negative numbers) [21, 47]. Each mini-game also involves one of the following *problem types*:

1. **NumberLine** - locate the position of a given decimal number on the number line.

2. **Addition** - add two decimal numbers by entering the carry digits and the result digits.
3. **Sequence** - fill in the next two numbers of a given sequence of decimal numbers.
4. **Bucket** - compare given decimal numbers to a threshold number and place each decimal in a “less than” or “greater than” bucket.
5. **Sorting** - sort a given list of decimal numbers in ascending or descending order.

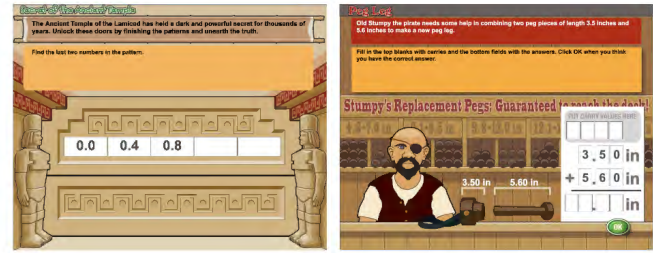

Figure 1: A screenshot of the main map screen.

In each theme area, and across the different theme areas, the problem types are interleaved to improve mathematics learning [41] and introduce variety and interest in gameplay. Figure 2 shows the screenshots of two mini-games - *Ancient Temple* (a **Sequence** game) and *Peg Leg Shop* (an **Addition** game). Each mini-game requires students to solve up to three problems of the same type (e.g., place three numbers on a number line, or complete three number sequences). Students must answer correctly to move to the next mini-game; they also receive immediate feedback about their answers. To further support learning, after a problem has been solved, students are prompted to self-explain their answer by selecting from a multiple-choice list of possible explanations [7].

A prior study by [34] showed that *Decimal Point* promoted more learning and enjoyment than a conventional instructional system with identical decimal content. Follow-up studies by [37] and [19] then tested the effect of student agency, where students can choose the order and number of mini-games they play. These studies revealed no differences in learning or enjoyment between low- and high-agency conditions, but [19] found that students in a high-agency condition had the same learning gains while playing fewer mini-games than those in low-agency, suggesting that the high-agency version led to more learning efficiency.

Post-hoc analyses by [52] examined the different mini-game sequences played by high-agency students and found that, consistent with the reports in [19], those who stopped early learned as much as those who played all mini-games. This result leads to important questions about the right amount of instructional content to maximize learning efficiency. To answer these questions, we would need a more fine-grained

measure of student learning using in-game data rather than external test scores. The KC modeling work presented here represents the first step in this direction.

(a) Ancient Temple (b) Peg Leg Shop

Figure 2: Screenshots of two mini-games.

2.3.1 Participants and Design

We obtained data from two prior studies of *Decimal Point* involving 484 students in 5th and 6th grade, in all study conditions [19, 37], and removed those students who did not finish all of the required materials, reducing the sample to 417 students (200 males, 216 females, 1 declined to respond). The students played either some or all of the 24 mini-games in Figure 1, depending on their assigned agency condition, as described previously. When selecting a mini-game, students would play two instances of that game, with the same interface and game mechanics but different questions. Students in the high-agency condition also had the choice to play a third instance of each mini-game once. In subsequent analyses, we use an index of 1, 2 and 3 to denote the instance number, e.g., *Ancient Temple 1*, *Ancient Temple 2* and *Ancient Temple 3*. For a detailed description of the experimental design of prior studies, refer to [19, 37].

2.4 Dataset

We analyzed students’ in-game performance data, which was archived in the DataShop repository [49] in dataset number 2906. The dataset covers a total of 613,055 individual transactions, which represent actions taken in the mini-games by 417 students in solving decimal problems.

3. METHODS & RESULTS

We started with the baseline KC models derived from two sets of features that *Decimal Point* was built upon. These initial models were fit using the Additive Factors Model (AFM) method [6], and the learning curves were visualized in DataShop. AFM is a specific instance of logistic regression, with student-correctness (0 or 1) as the dependent variable and with independent variable terms for each student, each KC, and the KC by opportunity interaction. It is a generalization of the log-linear test model [54] produced by adding the KC by opportunity terms. We then chose the model with better fit and analyzed its learning curves. Each model was run on 42,637 observations tagged with KCs.

3.1 Baseline Models

Our first baseline model, called *DecimalMisc*, consists of four KCs that are the misconceptions targeted by the mini-games: *Megz*, *Segz*, *Negz*, *Pegz* [21]. Because each mini-game was designed based on a single misconception (KC),

we created a model that maps each mini-game question to its corresponding KC. The second model, **ProblemType**, instead maps each mini-game question to its problem type (one of **NumberLine**, **Addition**, **Bucket**, **Sorting** and **Sequence**). Table 1 shows the fit statistics results of these two models.

Table 1: Fit statistics results of the two baseline models. RMSE indicates 10-fold cross-validation root mean squared error, stratified by item. Values that indicate best fit are in bold.

Model (# of KCs)	AIC	BIC	RMSE
DecimalMisc (4)	30,699.27	34,379.97	0.3292
ProblemType (5)	29,504.09	33,202.12	0.3231

As can be seen, **ProblemType** outperforms **DecimalMisc** in all three metrics - AIC, BIC and RMSE. In other words, the actual problem types capture students’ learning better than the underlying misconceptions. In subsequent analyses, we therefore focused on improving the **ProblemType** model. The first step is identifying potential improvements in the learning curve of each KC. In general, a good learning curve is smooth and decreasing [51]. Smoothness indicates that no step is much harder or easier than expected, and a decreasing curve shows that students were learning well and therefore made fewer errors at later opportunities [36].

From Figure 3, we observed that the learning curves of **NumberLine** and **Bucket** are reasonably good. The learning curve of **Addition** stays at roughly the same low error rate throughout ($< 10\%$), but there are sudden peaks, suggesting that some problems were harder than others and thus should be represented by a separate KC. The learning curve of **Sequence** decreases but not smoothly; the zigzag pattern indicates that students were alternating between easy and hard problems. Again, having separate KCs for the lows and highs of the curve would likely yield a better fit. The learning curve of **Sorting** is neither decreasing nor smooth; therefore, this KC needs to be further decomposed.

3.2 Improved KC Models

3.2.1 KC decomposition

To find possible decompositions, we followed the human-machine discovery method outlined in [51] and consulted prior literature on students’ learning of decimal numbers. Below we present our analysis of each problem type.

NumberLine. As its learning curve is already good, we turned to related work on the game *Battleship Numberline* [29], where students have to place given fraction numbers on a number line. The authors found that, on a number line that runs from 0 to 1, students have better understanding when adjusting from 0 or 1 (e.g., $1/10$ or $9/10$) than from $1/2$ (e.g., $3/7$). Since decimal numbers can be translated to fractions and vice versa, we (tentatively) experimented with applying the findings of [29] to our model. In particular, we decomposed the **NumberLine** KC into **NumberLineMid** (the number to locate lies between 0.25-0.75) and **NumberLineEnd** (the number to locate lies between 0-0.25 or 0.75-1).

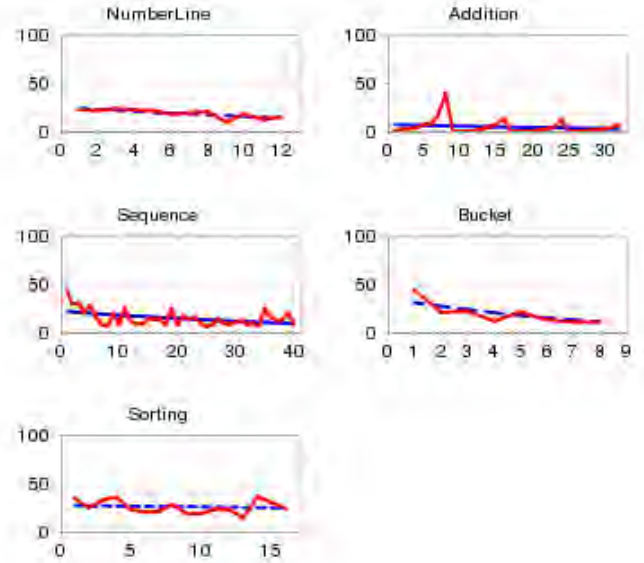

Figure 3: Learning curves of the KCs in ProblemType. The x-axis denotes opportunity number for each KC and y-axis denotes error rate (%). The red line plots all of the actual students’ error rate at each opportunity, while the blue line is the curve fit by AFM.

Addition. There are eight items in an **Addition** game: four text boxes for carry digits - *carryTens*, *carryOnes*, *carryTenths*, *carryHundredths* - and four text boxes for the result - *ansTens*, *ansOnes*, *ansTenths*, *ansHundredths* (see Figure 2b for an example). Previously, all of these items had the same KC label of **Addition**, but we expected that some digits would be harder to compute than others. For instance, the *carryHundredths* digit is always 0, because our problems only involve numbers with two decimal places. On the other hand, because the focus of **Addition** problems is to test that students can carry from the decimal portion to the whole number portion (i.e., probing for the **Pegz** misconception), the *carryOnes* digit is always expected to be 1. It was indeed the case that *carryOnes*, along with *ansOnes*, accounts for a large portion of the peaks in **Addition**’s learning curve (Figure 3). The most common error in these peaks, however, comes from *carryTens* and *ansTens* in the mini-game *Thirsty Vampire 1*. For the majority of students in our sample (87.5%), *Thirsty Vampire 1* was the first **Addition** problem they encountered, and its question ($7.50 + 3.90$) was also the only one with a carry in the tens place; in other words, it was both the first and hardest question. For this reason, we decided to decompose the **Addition** KC into:

- **Addition_Tens_NonZero** applies to the *carryTens* and *ansTens* item in *Thirsty Vampire 1*.
- **Addition_Ones** applies to *carryOnes* and *ansOnes* in all **Addition** mini-games.
- Other items (e.g., *carryTenths*, *carryHundredths*, *ansTenths*) retain the KC label **Addition**.

Sequence. In a **Sequence** mini-game, students have to enter the last two numbers in an increasing arithmetic se-

quence, based on the pattern of the first three given numbers (e.g., Figure 2a). In the way the questions were designed, the first number to fill in always requires an addition with carry, whereas the second does not involve a carry. We therefore hypothesized that the first number is more difficult than the second, which was confirmed by inspection of the learning curve: the alternate up and down patterns depict students' error rates as they filled in the first and second number in each sequence. We further distinguished between numbers with two decimal digits and those with one, as the former should be more difficult to work with. In summary, we decomposed the **Sequence** KC into four KCs: **Sequence_First_OneDigit** (first number, with one decimal digit), **Sequence_First_TwoDigits** (first number, with two decimal digits), **Sequence_Second_OneDigit** (second number, with one decimal digit), **Sequence_Second_TwoDigits** (second number, with two decimal digits).

Bucket. As the learning curve of **Bucket** is already good, we did not further decompose this KC.

Sorting. The learning curve of **Sorting** remains flat at around a 25% error rate. Since there are no outstanding blips or peaks in this curve, we instead used DataShop's Performance Profiler tool to plot the predicted and actual error rates of each mini-game problem (Figure 4). We identified five mini-game problems in which the actual error rate was larger than predicted by at least 5%; in other words, these problems were harder than expected. Therefore, we labeled five of them - *Rocket Science 1*, *Rocket Science 2*, *Jungle Zipline 2*, *Balloon Pop 2* and *Whac A Gopher 1* - by a separate KC called **SortingHard**, while other problems remained in **Sorting**. We will characterize the mathematical features of these **SortingHard** problems in Section 4.2.

Figure 4: Visualization of the **Sorting KC's goodness of fit with respect to ten **Sorting** mini-games with the highest error rates. The bars (shaded from left) show the actual error rates and the blue line shows predicted error rates.**

3.2.2 New model result & comparison

Table 2 shows the fit scores of the original **ProblemType** model, the models resulting from individual KC decompositions, and the final model combining all decompositions, called **Combined**. Apart from **ProblemType** and **Combined**, the name of each other model indicates which original problem type KC is decomposed. For instance, the **Sorting** model has six KCs - **SortingHard**, **Sorting**, **NumberLine**, **Bucket**, **Addition**, **Sequence** - where the last four are identical to those in **ProblemType**. We can therefore see that

decomposing the original **Sorting** KC alone results in a decrease of AIC by 231.91 and BIC by 214.59.

Table 2: Fit statistics results of the original and new models, sorted by AIC in descending order. Values that indicate best fit are in bold.

Model (# of KCs)	AIC	BIC	RMSE
ProblemType (5)	29,504.09	33,202.12	0.3231
NumberLine (6)	29,492.48	33,207.83	0.3233
Sorting (6)	29,272.18	32,987.53	0.3215
Sequence (8)	29,159.27	32,909.25	0.3234
Addition (7)	29,025.77	32,758.43	0.3235
Combined (12)	28,436.07	32,255.34	0.3196

Figure 5 shows the resulting learning curves of the above decompositions. We observed three KCs with issues: (1) **Sequence_First_TwoDigits** is a flat curve which indicates no learning, (2) **SortingHard** remains at high error rates, and (3) **Addition_Tens_NonZero** has too little data (because it only applies to *Thirsty Vampire 1*). Three other KCs - **Addition**, **Addition_Ones**, **Sequence_Second_Digits** - have low and flat curves, suggesting that students already mastered them early on and did not need as much practice (i.e., they were over-practicing with these KCs). The remaining KCs have smooth and decreasing curves. Most notably, we were able to fix the zigzag pattern in the original **Sequence** curve, reduce the peaks in the **Addition** curve, and capture the **Sorting** problems that do reflect students' learning.

Other than **NumberLine**, all of the new models resulted in better AIC and BIC scores. The **Combined** model, which incorporates all decompositions, is the best fit; when compared to **ProblemType**, its AIC score is lower by 1068.02 and its BIC is lower by 946.78. Using DataShop's Performance Profiler tool, we were also able to visualize the differences between these models in Figure 6. Here we see that for each of the new KCs, the **Combined** model's prediction, represented by the blue line (square points), is closer to the actual error rate than the **ProblemType** model's prediction, represented by the green line (round points). Hence, the combination of our KC decompositions resulted in a better fit visually.

4. DISCUSSION

4.1 Comparison of Baseline Models

We found that the **ProblemType** model, which maps mini-game questions to problem types, is a better fit for student learning than the **DecimalMisc** model, which maps mini-game questions to underlying misconceptions. Here we outline two possible interpretations.

First, while each question was designed to test one misconception, students may demonstrate other misconceptions in their answers. For example, the mini-game *Jungle Zipline 1*, labeled as **Segz** (shorter decimals are larger), asks students to sort the decimals 1.333, 1.33, 1.3003, 1.3 from smallest to largest. An answer of 1.3003, 1.333, 1.33, 1.3 would match

KCs with issues

Low and flat KCs

Good KCs

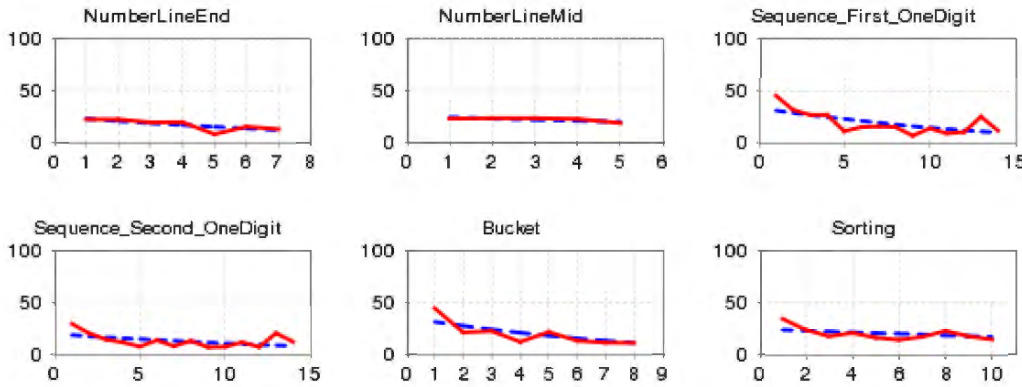

Figure 5: Learning curves of the KCs in Combined. The x-axis denotes opportunity number and y-axis error rate (%). The red line plots the actual students' error rate at each opportunity, while the blue line is the curve fit by AFM.

Figure 6: Visualization of the Combined and Problem-Type models' goodness of fit with respect to the new KCs. The bars (shaded from left) show the actual error rates. The blue and green line show predicted error rates of Combined and ProblemType respectively.

the *Segz* misconception, but we observed that 25% of the incorrect answers were 1.3, 1.33, 1.333, 1.3003, which instead corresponds to *Megz* (longer decimals are larger). As another

example, the mini-game *Capture Ghost 1*, labeled as *Megz*, asks students to decide if each of the following numbers - 0.5, 0.341, 0.213, 0.7, 0.123 - is smaller or larger than 0.51. 14% of the incorrect answers stated that $0.5 > 0.51$ and also $0.341 > 0.51$, which demonstrates both *Segz* and *Megz*, respectively. In general, in a problem solving environment like *Decimal Point*, measuring students' misconceptions should be based on their actual answers, not the questions alone. Therefore, a KC model that maps each question to its hypothesized misconception may not capture the students' full range of learning difficulties. Two alternative approaches used by other research for tracking decimal misconceptions are: (1) measuring them at a larger grain size, such as *whole number*, *role of zero* and *fraction* [14], and (2) using erroneous examples instead of problem solving questions [21]. In the context of KC modeling, we could apply our process to an existing dataset of student learning of decimal numbers from erroneous examples, such as the dataset from [33].

From a cognitive perspective, [44] pointed out that "different kinds of knowledge and competencies only show up intertwined in behavior, making it hard to measure them validly and independently of each other." The authors conducted

a series of studies to test students' conceptual knowledge of decimal numbers and procedural knowledge of locating them on a number line. Each study employed four common hypothetical measures of each kind of knowledge, but revealed substantial problems with the measures' validity, suggesting that it is difficult to reliably separate tests of conceptual knowledge and procedural knowledge. In our context, the decimal misconceptions reflect conceptual knowledge while the problem types require a combination of both conceptual and procedural knowledge. Therefore, differentiating problems by their types creates clearer KC distinctions than by their associated misconceptions, because the former matches more closely with students' actual performance.

4.2 Interpretation of the New KCs

Here we discuss the insights from our earlier KC decomposition results, using a combination of learning curve analyses and domain-specific interpretations. While the example questions we cite are specific to those in *Decimal Point*, the findings about student learning are applicable to any other educational technology system in decimal numbers.

NumberLine. Unlike [29], we did not observe that students have more difficulty with numbers close to 0.5 than with numbers close to 0 or 1. Decomposing **NumberLine** into **NumberLineEnd** and **NumberLineMid** results in increases in BIC and RMSE, which are indicative of overfit. Furthermore, the original learning curve of **NumberLine** is already smooth and decreasing (Figure 3), so it is unlikely that any decomposition would yield significant improvements. More generally, this result suggests that students could learn to estimate the magnitude of a given decimal number between 0 and 1 reasonably well, even though they may have difficulty with the equivalent fraction form in the way [29] reported. To explain this difference, we should note that students tend not to perceive decimals and fractions as being equivalent [47], hence difficulties with fractions may not translate to difficulties with decimal numbers. As [12] pointed out, a fraction a/b represents both the relation between a and b and the magnitude of the division of a by b , whereas a decimal number, without the relational structure, more directly expresses a one-dimensional magnitude. Therefore, students often have higher accuracy in estimating decimal numbers than fractions on a number line [53]. The findings from our analysis and [29] further support this distinction.

Addition and Sequence. These problem types both involve computing the sum of two decimal numbers, and as our decompositions showed, the difficulty factor lies in carrying digits to the next highest place value. In the case of **Addition**, the first question, which also happens to be the most challenging, is to add 7.50 and 3.90, which requires two carries, one to the ones place and one to the tens place. The error rate is therefore highest for this question (the first peak in Figure 3), but decreases at later (easier) opportunities. The original learning curve of **Sequence** problems has a zigzag pattern due to the students alternating between additions with and without carry. Distinguishing between these two types of operations, and also on the number of decimal digits, did result in a better model fit. We also note that the error rates in **Sequence** problems are generally higher than in **Addition** problems. A possible interpretation is that, while the underlying addition operations are similar,

the **Sequence** interface does not lay out the carry and result digits in detail as the **Addition** interface does (Figure 2). As pointed out by [25], for adding and subtracting decimals of different lengths, incorrect alignment of decimal operands is the most frequent source of error. Since **Addition** problems already supported this alignment via the interface, students were less likely to make mistakes in them.

Bucket and Sorting. These problem types both involve performing comparisons in a list of five decimal numbers, but in different manners. **Bucket** problems require comparing each number to a given threshold value, while **Sorting** problems require comparing the numbers among themselves. According to [40], ordering more than two decimals (**Sorting**) could reveal latent erroneous thinking which mere comparison of pairs (**Bucket**) cannot. Consistent with this finding, our results also showed that students were able to learn **Bucket** problems well but struggled with **Sorting**. Our hypothesis is that a **Sorting** problem requires two separate skills: (1) comparing individual pairs of number (in a list of five numbers, students may perform up to ten comparisons), and (2) ordering the numbers once all the comparisons have been established. The current interface only asks for the final sorted list, so it would need to be redesigned to allow for tracking student mastery of each of these two skills. Furthermore, by examining the five problems categorized as **SortingHard**, we identified unique challenges that were not present elsewhere in *Decimal Point*. First is the issue of negative number - the mini-game *Balloon Pop 2*, with an error rate close to 60% (Figure 4), asks students to sort the sequence 8.5071, -8.56, 8.5, -8.517 in descending order. Given that students may hold misconceptions about both the length and sign of decimal numbers [21], and that no other **Sorting** problems involve negative numbers, it is clear why students faced significant difficulties in this case. The second issue is another common misconception - that a 0 immediately to the right of the decimal point does not matter (e.g., $0.03 = 0.3$) - which [39] referred to as *role of zero*. It could be invoked in the mini-game *Rocket Science 1*, which asks students to sort 0.14, 0.4, 0.0234, 0.323 in ascending order; in particular, 19% of the incorrect answers put 0.0234 between 0.14 and 0.323, implying the incorrect belief that $0.0234 = 0.234$. Previous studies have also reported that 9th graders and even pre-service teachers demonstrated this misconception in similar sorting tasks [20, 38]. Furthermore, students may still have this misconception even after abandoning others [13].

According to [24], there are four steps to redesign a tutor based on an improved cognitive model: (1) resequencing, (2) knowledge tracing, (3) creating new tasks, and (4) changing instructional messages, hint and feedback. Based on this framework and our analyses, we derived the following lessons for designing instructional materials in our digital learning game and other tutoring systems in decimal numbers:

1. Arrange the easy **Addition** problems (without or with one carry) at the beginning. The number of these easy problems can also be reduced, as over practice is already occurring based on the number of problems students are attempting with low error rates.
2. Design more **Addition** problems with varying difficulties (those with more carries are more difficult) and

position them in increasing order of difficulty.

3. Leave the operand fields blank in **Addition** problems so that students can practice aligning decimal digits. Getting feedback on this alignment task could in turn help them solve **Sequence** problems better.
4. Provide more scaffolding in **Sorting** problems, by first asking students to perform pairwise comparisons of the given numbers, then having them place the numbers in order. The first task can be used to track misconceptions and the second to track the skill of ordering.
5. Design questions in other problem types besides **Sorting** (e.g., **NumberLine**, **Bucket**) that address the *role of zero* misconception, as it may be stronger and persist longer than other misconceptions.

4.3 Advantages of Post-hoc KC Modeling

While, in general, KC modeling methods can be applied to any domain, domain knowledge is still critical for the interpretation of the improved models and an understanding of the newly discovered KCs. We have shown that we can apply methods in a post-hoc manner to a dataset in an educational domain to both achieve a better understanding and create a better fitting KC model. Our findings also demonstrate that the type of KC modeling we used can help guide changes to the types, contents and order of problems that are used in a decimal learning game (and educational technology more generally). From a theoretical perspective, the search space for a KC model in a given domain will be somewhere between a Single KC model, where every step represents the same KC, to a Unique Step model, where every step has its own KC. If we include the option of tagging a single step with multiple KCs, the space could get infinitely larger, but in a practical sense multi-coded steps could be combined to a single KC by concatenating the KCs on a given step. Several automated processes have been applied to create KC models by searching the possible space, such as Q-Matrix search [48], but they have the limitation of creating models with unlabeled skills. The methods that we used do not face this problem because we started with a fully labeled model and worked from there. Using visual and computational analyses on the learning curves, we were able to make improvements by combining the output of fitting models with domain knowledge. The original **Addition** KC is an excellent example of this approach in action. While the overall curve did show a declining error rate, every four opportunities looked as if the steps were getting harder (see Figure 3). Methodologically, this was a clear opportunity for improvement and likely a feature where each successive step in a problem became harder. Sure enough, this was the case as each of four problem steps required a carry, and the hardest problem required two carries. This is one example which demonstrates that we were able to not only get a better fitting model, but also attain a deeper domain understanding.

4.4 Future Work

In our next study, we will use the best KC model from this work as a test of how well it performs with a new population of students. There is also potential in connecting our work with earlier studies of student agency in digital learning games. In particular, [37] and [19] reported that even though students in the high-agency condition could choose to play any mini-game in any order, they did not learn more than those in the low-agency condition, who played a fixed

number of mini-games in a default order. [19] speculated that the former might be focused on selecting mini-games based on their visual themes (e.g., *Haunted House*, *Wild West* - see Figure 1) rather than learning content. To address this issue, we could employ an open learner model [4] that displays the estimated mastery level of each decimal skill to the students, where the skills are the KCs in our best model. In this scenario, we expect that students who exercise agency would be able to make informed selections of mini-games based on an awareness of their learning progress.

At the same time, digital learning games are intended to engage students and promote learning. Therefore, we want to explore the interactions between enjoyment and learning, particularly in how best to balance them. Just as learning can be modeled by knowledge components, can enjoyment also be modeled by “fun components,” and how would they be identified? We believe our digital learning game is an excellent platform for this exploration, because each mini-game has a separate learning factor (the decimal question) and enjoyment factor (the visual theme and game mechanics). It is also possible to track students’ enjoyment either through in-game surveys or automated affect detectors [1]. As our next step, we will design two study conditions, one that employs a traditional open learner model and one that captures and reflects students’ enjoyment, using the five problem types (worded in a more playful way, e.g., **Shooting** instead of **Sorting**, because all **Sorting** mini-games involve shooting objects such as spaceship) as the initial fun components. Findings from this follow-up study would then allow us to refine our enjoyment model and provide insights into whether a learning-driven or enjoyment-driven game design yields better outcomes.

In the direction of KC modeling, as mentioned in [19] and [52], it is possible that the the game contains more learning materials than required for mastery, or that some students may have exhibited greater learning efficiency than others. With the KC model identified in this work, we can then apply Bayesian Knowledge Tracing [11] to assess students’ mastery of each KC and verify the presence of learning efficiency or over-practice. Another area we plan to study is whether individual differences among the students in their gameplay and learning could lead to further improvement in predicting skill mastery based on the best-fit KC model, similar to previous research done in an intelligent tutor for genetics learning [15]. These individual differences could be accounted for by other features in the game outside of the identified cognitive-defined KCs [16].

5. CONCLUSION

Previous work has been done on refining KC models for educational systems in the manner we have shown here [51], although our research focused on the application of the refinement techniques to a digital learning game. We found that modeling KCs by problem types yields a better fit than modeling by the underlying misconceptions that were being tested. Furthermore, the refined KC model also showed us how to improve the original learning materials, in particular by focusing on the more challenging and persistent misconceptions, such as those involving multiple carries, role of zero and negative numbers. More generally, we demonstrated how learning curve analysis can be employed to perform

post-hoc KC modeling in a tutoring system with various types of task. In turn, our work opens up further opportunities to explore the interaction of student models with learning, enjoyment and agency, which would ultimately contribute to the design of a learning game that can adaptively balance these aspects.

6. ACKNOWLEDGEMENTS

This work was supported by NSF Award #DRL-1238619. The opinions expressed are those of the authors and do not represent the views of NSF. Special thanks to J. Elizabeth Richey and Erik Harpstead for offering valuable feedback. Thanks to Scott Herbst, Craig Ganoe, Darlan Santana Farias, Rick Henkel, Patrick B. McLaren, Grace Kihumba, Kim Lister, Kevin Dhou, John Choi, and Jimit Bhalani, for contributions to the development of the Decimal Point game.

ABSTRACT

Collaborative problem solving in computer-supported environments is of critical importance to the modern workforce. Coworkers or collaborators must be able to co-create and navigate a shared problem space using discourse and non-verbal cues. Analyzing this discourse can give insights into how consensus is reached and can estimate the depth of their understanding of the problem. This study uses Coh-Metrix, a natural language processing tool that measures cohesion, to analyze participant discourse from a recent multi-modal learning analytics study where novice programmers collaborated to use a block-based programming language to instruct a robot on how to solve a series of mazes. We significantly correlated thirty-five Coh-Metrix indices from the transcripts of dyads' discourse with collaboration, learning gains, and multimodal sensor values. We then fit a variety of machine learning classifiers to predict collaboration using the indices generated by Coh-Metrix as features. This study paves the way for real-time detection of (un)productive interactions from multimodal data and could lead to real-time interventions to support collaborative learning.

Keywords

Collaboration, computer-supported collaborative work, multi-modal learning analytics, Coh-Metrix.

1. INTRODUCTION

Collaborative problem solving with computer-based or computer-supported environments has long been a focus of research on educational technologies [1] and is now seen as a 21st century learning objective of critical importance to the workforce [2]. Discourse of collaborators who co-create and navigate a shared problem space can give insights into how consensus is reached and the depth of their understanding. Because qualitative coding of transcripts or video is laborious and time-consuming, capturing and quantifying the quality of social interactions remains a challenge in the social sciences.

Joseph Reilly and Bertrand Schneider "Predicting the Quality of Collaborative Problem Solving Through Linguistic Analysis of Discourse" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 149 - 157

Applied natural language processing can automate the analysis of large corpora of human language and is a foundational technique of educational data mining. Coh-Metrix [3], a tool originally developed to measure text difficulty, has been used to evaluate online discussion transcripts and intelligent tutoring system dialogue. By applying the tool to discourse from a collaborative problem-solving activity, we hypothesize that certain markers can indicate the quality of the collaboration and could be used to predict how well groups work together from their speech patterns.

This paper uses Coh-Metrix to analyze participant discourse from a recent multi-modal learning analytics (MMLA) [7] study where novice programmers used a block-based programming language to program a robot to solve a series of mazes [4]. Preliminary results from this study indicate the importance of speech equity and talking time; however, the full transcripts of the discourse have not yet been analyzed. In this paper, we explore multiple indices from the transcripts that are correlated with collaboration, learning gains, and multimodal sensor values. We then explore ways of predicting collaboration using the indices generated by Coh-Metrix as features fed into a variety of machine learning classifiers. Finally, we discuss these results and conclude with future avenues for this research.

2. LITERATURE REVIEW

A few decades ago, computer-supported collaborative learning (CSCL) emerged as a statement against the over-individualization of educational technology, emphasizing that collaborative learning can be fostered by carefully designed computer-supported activities [5]. Collaboration analysis in computer-supported environments has explored what facets of collaborative processes are essential for successful problem-solving and learning [29] with a particular emphasis on what aspects of these analyses can be automated [30]. When studying the process of collaboration, a 'Joint Problem Space' emerges that takes the form of a socially-negotiated knowledge structure that combines goal-setting, descriptions of the problem, and available actions [1]. This problem space can be understood through discourse analysis in conjunction with any other data collected on group behaviors.

In the search for new tools to analyze and model interactions between collaborators [6], Multi-Modal Learning Analytics (MMLA) has emerged. Sensors continue to get cheaper and easier to use while providing rich streams of data which can be used in conjunction to track and assess collaboration [7]. Data from multiple high frequency sensors can triangulate difficult to measure constructs and enhance overall predictive performance [31]. Analyzing features engineered from sensor data as well as dyadic

discourse provides a deeper view of the joint problem space, which includes nonverbal communication, posture, eye gaze, and arousal, among other possible metrics.

Coh-Metrix is an online tool that measures 106 linguistic features related to text easability, cohesion, lexical sophistication, syntactic complexity, and readability [3]. To differentiate between coherence and cohesion, the developers of this tool view cohesion as a quality of the text or discourse that can be directly measured, while coherence is in the mind of the reader [8]. The Coh-Metrix indices generally indicate the presence or absence of cohesive cues that tie the text together and make it easier or harder to understand. The tool focuses on local and overall text cohesion versus global cohesion [9].

Coh-Metrix has mainly been used in analyzing text readability and writing quality but has been applied successfully to other domains as well. Its indices have been used to detect lying in online discourse with one group member specified as sender and other as the receiver [10]. Tutor dialogue in AutoTutor was compared to naturalistic dialogue with a human tutor using Coh-Metrix to see how the dialogues differed on cohesion indices [11]. Indices for cohesion were also used to train affect detectors for AutoTutor users with the intention of developing real-time affect detectors based on cohesion [12]. The tool has also been used with online discussion transcripts to classify online discourse for levels of cognitive presence, and a classifier using Coh-Metrix features outperformed a similar algorithm using bag-of-words features [13].

Rarely do Coh-Metrix studies use transcripts of oral dialogue or assume participants are both novices (i.e. the task is not an expert-novice tutoring scenario.) Additionally, these indices have been sparingly used in MMLA research. In an MMLA study on a similar collaborative task, verbal coherence positively correlated with learning gains and significantly differed by condition [14]. Researchers then used language metrics to predict learning gains via support vector machine (SVM). Initial work from this current study has indicated that amount of talking and equity of talk time may be important indicators of good collaboration [15] but this discourse has not been analyzed in-depth yet.

3. RESEARCH QUESTIONS

This study attempts to answer the following research questions (RQs):

RQ1: Are Coh-Metrix indices derived from transcripts of discourse between co-located partners related to the quality of their

collaboration and learning gains?

RQ2: Are Coh-Metrix indices different across experimental conditions?

RQ3: Are Coh-Metrix indices associated with MMLA measures (e.g., Joint visual attention, physiological synchrony, nonverbal behaviors) that were previously significantly correlated with collaboration quality?

RQ4: What Coh-Metrix indices are most meaningful for estimating a group's collaboration?

RQ5: Can Coh-Metrix indices be used to train supervised machine learning algorithms to predict collaboration quality?

4. METHODS

4.1 The Study

Participants with no self-reported prior programming or robotics knowledge ("novices") were paired randomly with an unknown partner and tasked with programming a robot to solve a series of increasingly complex mazes in 30 minutes. During the activity, mobile eye-trackers recorded participant gaze data, bracelets captured electrodermal activity, and a motion sensor collected movement and position data. A 2x2 study design was employed to test two different collaboration interventions: an informational intervention that described the benefits of collaborating on tasks and a visualization intervention that graphically plotted relative verbal contributions from each participant from the previous 30 seconds. The informational intervention is the primary on discussed here as the other did not result in significant differences in dependent measures. All participants gained knowledge of basic programming skills according to a pre-post survey ($t = 6.18$, $p < 0.001$) and a 7 percentage point increase in collaboration quality was associated with a 2 percentage point increase in code quality when controlling for gender and prior education ($p < 0.001$). For more details of experimental design and overall results, see Table 1 and [4]. Figure 1 shows a typical image of the experiment in progress.

4.2 Participants

Forty-two dyads completed the study and the first sessions each researcher conducted were removed to improve overall fidelity ($N = 40$ groups). Participants were drawn from an existing study pool at a university in New England in the United States. 62% of participants reported being students at the university of various levels, with ages ranging from 19 to 51 years old with a mean age

Table 1. Summary of measures from study.

Independent Measures	Process Data	Dependent Measures
Control Condition: no intervention	Eye-tracking: Joint visual attention by dyads on different areas of interest, amounts of time looking at areas of interest	Expert ratings of collaboration
Treatment Condition: informational intervention orally delivered by researcher prior to beginning of main portion of study.	Electrodermal activity: differences between individuals, synchrony measures, rates of change	Task performance measures
	Movement and posture: proximity, alignment, bimanual coordination, total movement, leaning, synchrony measures	Survey gains

Figure 1. Experimental setup from the study.

of 27 years. 60% of participants identified as female. Participants were paid \$20 per 90-minute session of the study.

4.3 Procedure

Prior to the main activity, participants signed informed consent paperwork and took a 5-minute pre-survey pertaining to simple programming tasks. Once the survey was complete, sensors were applied to the participants and calibrated while the function of each sensor was explained.

Next, participants were shown a tutorial video explaining how to write code in Tinker, a block-based environment designed for use with the sensors and motors on the robot. Participants were then given 5 minutes to write a simple program to move the robot forward past a red line on the table in front of them. After the completion of this tutorial activity, participants were shown a second tutorial video that explained more advanced features of the programming environment like setting threshold sensor values for triggering commands and using conditional statements. A reference sheet was also provided to participants that summarized the content of both tutorial videos.

At this point, groups in the Intervention condition were read a summary of several research findings relevant to collaboration such as the importance of equity of speech time in high quality collaboration. Dyads in the Control group were given no such information after completing the tutorial ($N = 20$ groups in each condition).

Dyads then had 30 minutes to write code to guide their robot through a series of increasingly complex mazes. Participants did not know the arrangement of the mazes ahead of time and were prompted to write code that could solve any simple maze. Once the robot completed a maze twice successfully, the next one was provided by the researcher. During this portion of the activity, predetermined hints were provided to groups at 5-minute intervals to ensure common pitfalls identified in pilot testing were avoided. Following the completion of this portion, the post-survey was administered, demographic data was collected, sensors were removed, and participants were paid and debriefed.

4.4 Dependent Measures

Dyads' collaboration was evaluated live by the researcher conducting the session. Quality of collaboration was assessed on nine different scales derived from Meier, Spada, and Rummel's work on assessing collaboration in CSCL [16]: sustaining mutual understanding, dialogue management, information pooling, reaching consensus, task division, time management, technical coordination, reciprocal interaction, and individual task orientation.

Each scale was on a -2 to 2 scale, and all scales were added together to generate an overall collaboration rating for dyads. Multiple researchers conducted sessions of the study and thus coded dyads' behavior. Researchers double coded 20% of the sessions from videos collected during the session and achieved an inter-rater reliability of $\alpha = 0.65$ (75% agreement).

Learning of computational skills (identifying a bug in block-based code, anticipating the output of a code segment, describing how to do a task with pseudocode, etc.) was assessed individually via pre- and post-tests with four questions each. These measures were adapted from [17, 18]. Researchers coded a subset of the responses to 100% agreement based on their demonstrations of understanding of computational thinking principles then coded the remaining surveys with the developed rubric.

4.5 Data Pre-Processing

Data collected by the eye-trackers, wristbands, and motion sensors each needed to be processed individually prior to merging for analysis. See Reilly, Ravenell, and Schneider for details on the processing of the Kinect motion sensor data [15] and Dich, Reilly, and Schneider for use of the electrodermal activity data from the Empatica E4 bracelet [19]. Four different physiological synchrony measures were calculated for movement and electrodermal (EDA) data: Signal Matching (SM), Instantaneous Derivative Matching (IDM), Directional Agreement (DA) and Pearson's Correlation (PC). SM was calculated as the differences in area between the plots of the team members' EDA, IDM calculates how closely the slopes of the physiological signal curves match, DA identifies whether individuals' signal data increase or decrease at the same time, and PC looks for a linear relationship between EDA data of both participants. For details on the calculation of these measures, see [19].

For use in this study, the eye-tracking data was summarized in two different ways: The proportion of time both participants were looking at the same spot (joint visual attention, see [20]) and the proportion of time spent looking at various areas of interest around the room (the computer screen, the maze, the robot, etc.) as determined by the fiducial markers placed on all objects in the experiment.

Audio recordings of sessions were transcribed using multiple iterations of assignments to Amazon Mechanical Turk workers until it was suitable for analysis. Transcripts were formatted via Python to match the requirements of Coh-Metrix and were sent to the Institute for Intelligent Systems at the University of Memphis for analysis. All analyses in this study were done in Python using the scikit-learn package [25].

5. RESULTS

5.1 RQ1: Correlations with Collaboration

Indices positively correlated with our rating of collaboration include more dialogue between partners (as measured by the number of sentences and words uttered), the use of adverbs, the CELEX word frequency (how often content words appear in sentences), and the familiarity of content words used. Deep cohesion (the use of causal connectives to signify causal relationships) and increased temporality (cues about temporality and tense) were also significantly positively correlated with collaboration. Additionally, the Coh-Metrix L2 readability score (use of simple grammar that an English language learner could

more easily parse) was also positively correlated. An appendix with definitions of all indices discussed here is provided at the end of this paper (also available in Appendix A of [3]). Significant correlations are listed in Table 2.

Table 2. Indices correlated with collaboration (red indicates negative correlation).

Index	Value (p-value)	Description
DESSC	0.51 (0.0087)	Descriptive indices that describe the number and length of paragraphs, sentences, and words
DESWC	0.735 (<0.0001)	
DESPL	0.51 (0.0087)	
DESWLsy	-0.27 (0.023)	
DESWLsyd	-0.36 (0.019)	
DESWLlt	-0.41 (0.0081)	
DESWLtd	-0.17 (0.016)	
PCNARz	0.53 (0.0042)	Text easability principal component scores
PCNARp	0.55 (0.0023)	
PCDCz	0.476 (0.039)	
PCTEMPz	0.53 (0.0068)	
PCTEMPp	0.52 (0.0064)	
PCCNCz	-0.41 (0.028)	
PCCNCp	-0.48 (0.0063)	
LDTTRc	-0.76 (<0.0001)	Lexical diversity (unique words per total number of words)
LDTTRa	-0.76 (>0.0001)	
LDVOD	-0.25 (0.047)	
CNCCaus	0.45 (0.037)	Incidence of connectives
CNCLogic	0.49 (0.042)	
CNCADC	0.36 (0.036)	
SMINTER	0.40 (0.044)	Ratio of intentional particles to intentional verbs
SYNNP	-0.43 (0.0012)	Number of modifiers per noun phrase, mean
DRPVAL	-0.33 (0.020)	Agentless passive voice density, incidence
WRDNOUN	-0.43 (0.0016)	Word information (part of speech category, syntactic categories)
WRDADV	0.47 (0.028)	
WRDPRP2	-0.68 (0.0005)	
WRDFRQc	0.43 (0.0004)	
WRDFRQa	0.16 (0.038)	
WRDAOAc	-0.28 (0.048)	
WRDFAMc	0.52 (0.0008)	
WRDCNCc	-0.46 (0.0063)	
WRDIMGc	-0.51 (0.007)	
WRDHYPv	-0.49 (0.0047)	
WRDHYPnv	-0.44 (0.0020)	
RDL2	0.36 (0.023)	Coh-Metrix L2 Readability

Indices negatively correlated with collaboration include the mean number of syllables per word, the number of nouns, the lexical diversity (unique number of total words), and hypernymy for nouns and verbs (using specific words instead of general ones.) Features that indicate the difficulty of understanding text are generally negatively correlated with collaboration, such as modifiers per noun phrase (complex syntax places higher demands on working memory), agentless passive voice, and the ratio of intentional

particles to intentional verbs (a higher ratio indicates more inference is needed to understand the text.) Indices for specificity of content words are also negatively correlated, such as concreteness and imageability (how easy it is to create a mental image of the word.)

5.2 RQ1: Correlations with Learning Gains

The magnitude of participant learning gains on the pre-post survey was also correlated significantly with several Coh-Metrix indices. Unlike collaboration, learning gain is positively correlated with lexical diversity ($r = 0.41$, $p = 0.041$) which indicates that use of specific language may aid learning of computer science principles. On the other hand, learning gain is negatively correlated with pronoun incidence ($r = -0.44$, $p = 0.041$) and referential cohesion ($r = -0.34$, $p = 0.049$) indicating that use of vague, overlapping language by the dyad is associated with lower gains on the survey.

5.3 RQ3: Differences by Condition

Differences between the Control and Intervention conditions could also be seen in their discourse during the activity. According to paired t-tests, groups in the Control condition had fewer words ($t = -3.4$, $p = 0.0019$), fewer adverbs ($t = -2.30$, $p = 0.029$), fewer sentences ($t = -2.17$, $p = 0.038$) and shorter paragraphs ($t = -2.17$, $p = 0.038$) than those in the Intervention condition. Additionally, the Control condition discourse had higher lexical diversity than the Intervention condition (LDTTRc: $t = 2.93$, $p = 0.0065$; LDTTRa: $t = 3.03$, $p = 0.0049$) which was shown above to be negatively correlated with collaboration.

With respect to the differences between groups that saw a visualization intervention that plotted relative verbal contributions from each participant, only the L2 Readability score differed significantly between conditions ($t = -2.16$, $p = 0.039$). As this intervention did not result in significant differences in our outcome measures, it makes sense that the impact on our Coh-Metrix indices is also minimal.

5.4 RQ4: Correlations with MMLA Values

We also explored whether any dyad-level features engineered from our sensor data might correlate with the Coh-Metrix indices that were previously seen to be significantly related to collaboration. Out of 30 features from our Kinect, eye-tracking, and EDA data, four were significantly correlated with three or more indices shown in Table 2. Correlation coefficients for these four features are shown in Figure 2.

From our eye-tracking data, the amount of time participants spent looking together at neither the maze nor the computer (aoi_0) was significantly negatively correlated with word length ($r = -0.42$, $p = 0.034$), lexical diversity ($r = -0.40$, $p = 0.042$), and syntactic complexity ($r = -0.39$, $p = 0.049$). Those three indices were also negatively correlated with collaboration. The amount of time participants spent looking at the maze and robot but not the computer (aoi_5) was positively associated with second person pronouns ($r = 0.65$, $p < 0.001$) and L2 readability ($r = 0.39$, $p = 0.047$) but negatively related to word length ($r = -0.42$, $p = 0.034$), word diversity ($r = -0.47$, $p = 0.016$), and use of the passive voice ($r = -0.40$, $p = 0.046$). This also follows a similar pattern to our correlations with collaboration.

The directional agreement (DA) of the dyad is calculated as the proportion of time where EDA for both participants was increasing or decreasing at the same time (in other words, it is a measure of

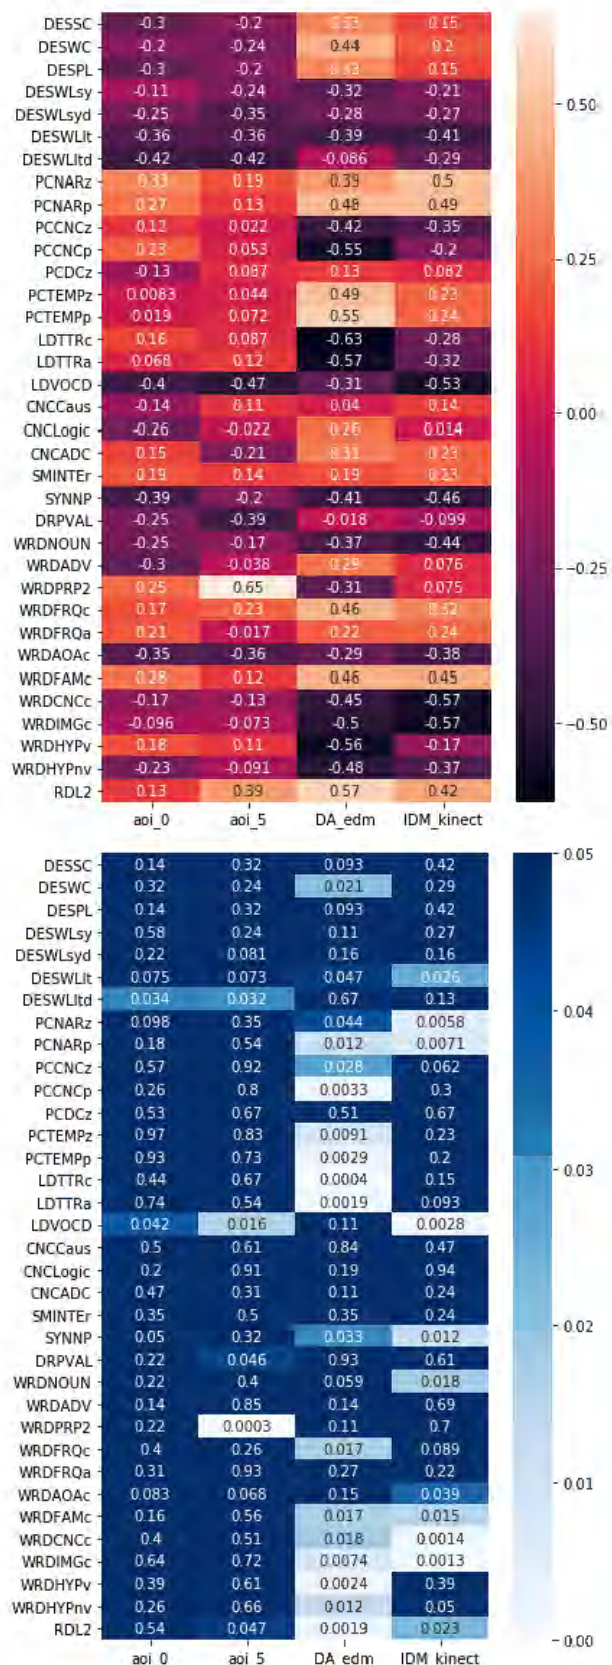

Figure 2. Correlation coefficients (top) and p-values (bottom) for select MMLA features.

physiological synchrony). Higher DA was positively associated with the number of words used ($r = 0.44$, $p = 0.021$), narrativity ($r = 0.48$, $p = 0.012$), temporality ($r = 0.55$, $p = 0.003$), word frequency ($r = 0.46$, $p = 0.017$), word familiarity ($r = 0.45$, $p = 0.017$), and L2 readability ($r = 0.57$, $p = 0.002$). DA was significantly negatively associated with lexical diversity ($r = 0.44$, $p = 0.021$), syntactic complexity ($r = -0.41$, $p = 0.033$), word concreteness ($r = -0.45$, $p = 0.018$), imageability of content words ($r = -0.50$, $p = 0.007$), and hypernymy ($r = -0.56$, $p = 0.002$). The directions of these correlations also fit with what we observed.

The Instantaneous Derivative Matching (IDM) of the Kinect movement data is calculated as the proportion of time where movement of both dyad members is either increasing or decreasing at a similar rate. IDM of movement was positively associated with narrativity ($r = 0.50$, $p = 0.006$), word familiarity ($r = 0.45$, $p = 0.015$), and L2 readability ($r = 0.42$, $p = 0.023$). Movement IDM was negatively correlated with word length ($r = -0.41$, $p = 0.026$), lexical diversity ($r = -0.53$, $p = 0.003$), syntactic complexity ($r = -0.46$, $p = 0.012$), the number of nouns used ($r = -0.44$, $p = 0.018$), word concreteness ($r = -0.57$, $p = 0.001$), imageability of content words ($r = -0.57$, $p = 0.001$), and hypernymy ($r = -0.37$, $p = 0.049$). Again, these correlations are of similar magnitude and direction as those seen in our results from collaboration.

5.5 RQ5: Predicting Collaboration

In order to explore how we might be able to use the Coh-Metrix indices to predict quality of collaboration, we classified dyads in terms of their collaboration ratings using a variety of typical machine learning classifiers. All 106 Coh-Metrix indices were used as features to classify the 40 groups. Missing values were imputed with their column means and all features were normalized prior to their use.

We first separated our participants into two groups based on the median value of group collaboration. We trained a Naïve Bayes classifier, a support vector machine (SVM), and a Random Forest (RF) model [21] on our entire data. NB usually works well with text data [26], SVM excels at binary classification [27], and RF along with other tree-based classifiers have been used successfully in the EDM community with a wide variety of educational datasets [28]. These algorithms were also selected as they are computationally rapid to implement once tuned and may be used in a real-time nature during a future intervention. The alpha, loss, and penalty used by SVM as well as the number of estimators, maximum depth, and criterion function for RF were selected by grid search with 5-fold cross-validation (CV). To address issues of overfitting with a small sample size, we report both training accuracy as well as the highest average accuracy achieved by our 5-fold cross-validation.

As shown in Table 2, the Random Forest model outperformed both Naïve Bayes and SVM on the binary classification median split task. While the 100% train accuracy of the RF is surely due to overfitting, the high CV accuracy. All algorithms were able to outperform random assignment by large margins. We next separated out participants into four groups based on the quartile values of group collaboration. Our three models were fit with the same procedure and once again RF outperformed both other algorithms on the training data. When looking at validation results, however, the RF and SVM classifiers performed identically. Simpler models may avoid the overfitting issues leading to the reported 100% training accuracy.

Table 2. Accuracy of classifiers.

	Median Split Train	Median Split CV	Quartile Split Train	Quartile Split CV
Naïve Bayes	0.88	0.74	0.81	0.51
SVM	0.88	0.75	0.84	0.53
Random Forest	1.00	0.84	1.00	0.53

To gain more insight into how these classifiers made their assignments, we investigated which features the RF model for the quartile split problem was ranking as most important for making assignments. Figure 3 plots the eleven most important features for our classification problem. Beyond that point, the feature importance rankings are too similar to derive insight. It is important to note that importance here is agnostic of whether these features correspond to good or bad collaboration; they are simply the most meaningful for deciding between them. Second person pronoun incidence (WRDPRP2) and lexical diversity (LDTTRc, as measured by the type-token ratio [22]) are the most important features. Word count (DESWC), sentence count (DESSC), incidence of negation expressions (DRNEG), text easability (PCDCp), and verb phrase density (DRVP) also rate highly. Many of these features were previously seen to be significantly correlated with collaboration, but verb phrase density and the incidence of negations appear here in our analyses for the first time.

**Figure 3. Feature importances for the quartile split Random Forest model.**

6. DISCUSSION

In general, our findings indicate that our strongest collaborating dyads communicated more in terms of amount of words and sentences as well as the length of each utterance before the other participant would interject. In addition, these groups used more abstraction when referring to content words and terms and employed basic words and grammar to convey meaning in a direct fashion. They avoided using the passive voice or pronouns while reaching a consensus on a simple shared set of words to describe the task and their actions. While synonyms and extraneous

modifiers were not used by strong collaborators, adverbs were used to define particular actions the robot needed to perform, and the use of logical, causal, and temporal connectives indicates a value to explicitly linking actions across space and time to meet the desired outcome. These indices of cohesion jointly allow collaborators to negotiate a shared problem space regardless of English language proficiency or level of education.

To ground the above findings, here is an example of a low collaborating dyad's discourse regarding programming the robot for a new maze:

A: So let's, we can do, no, yeah, we can put up, if yeah and if it's that then it goes this.

B: Then we add, turn right.

A: Yeah it will go right and then it will take for, wait for 10 seconds and then take a left. Also take a left.

B: Yeah, go, go forward. Go forward. Left, then we go straight.

A: Let's go forward. Left and then right. Then left and right.

In contrast, this is dialogue from a high collaborating group at a similar point in the activity:

C: So let's try changing this value to...greater than the second "If Do".

D: Okay. I just want to see if, oh, what did I do there, I just want to see if that what difference that makes.

C: Perfect. All right, are you ready?

D: Yep. Nope, all right.

C: Okay so, we've got it going forward and turning right so at least the right works. That one's correct now.

D: Now... if we change this number so let's go back to the widget.

C: Okay, okay. I think I've got it, so we needed to turn so when we got it turn right, we need to maybe check to if it turns left or right needs to be "greater than".

In the second dyad's discourse, more complete yet simple grammar and explicit markers of turn-taking result in a much fuller discourse that is easier to track. Their use of causal language and conditionals and implies a greater grasp of the content of the activity.

The importance and effects of cohesion are typically much higher for low-knowledge readers, with this relationship dubbed the "reverse cohesion effect" in discourse literature [23]. As none of our participants had any prior knowledge of robotics or computer programming, the importance of cohesion in participant discourse is likely to be crucial in similar educational settings. Reading skill and young age can also interact with this effect but these issues were not confounders in our study due to the use of oral dialogue and our population being solely adults.

As far as how the Treatment and Control groups differed, the Control groups typically communicated less (fewer sentences with shorter exchanges), used less adverbs, and had a higher lexical diversity (which was shown to be negatively correlated with collaboration). This difference shows that even simple verbal cues delivered as an intervention prior to an activity can have a positive association with collaboration by fostering more cohesive communication. The effect size of an informational intervention such as this on collaboration might be effectively used as a baseline when comparing more elaborate interventions in similar activities in the future. It is also reassuring to see the low effect on the Coh-Metrix indices from the visualization intervention condition that had no effect on collaboration. This validates our strategy of using

these indices without coding scheme to assess collaboration quality in a variety of different experimental conditions.

Comparing average learning gains on the pre-post survey to the Coh-Metrix indices is difficult for several reasons. First, the survey was done at the individual level and by only using the mean change we ignore when participants unequally learned during the task. Second, gains may be susceptible to ceiling effects where high gains are not seen due to high performance on the pre-test. Third, the dyads were instructed to program the robot to solve mazes and thus their conversation revolved around that task. The activity certainly utilized the computer science principles that were assessed in the survey, but the discussion was not as specific as a tutor dialogue regarding programming.

Despite these issues and challenges, several Coh-Metrix indices reveal what types of markers in the discourse can signal learning taking place. While lexical diversity was negatively associated with collaboration, it appears to be beneficial for learning. Knowing and applying more terms for phenomena or problem-solving strategies may aid participants transfer their knowledge from the experimental task to the post-survey. Additionally, too much referential cohesion may make ideas difficult to separate out of context and thus more challenging to use in isolation on test questions.

It is worth noting that features engineered from all three of our MMLA sensors provided insight into how to assess collaboration using the Coh-Metrix indices identified as significantly related to collaboration. When joint visual attention fell outside of the tabletop or laptop (aoi_0), this could generally be interpreted as participants looking at each other (as relatively little time was spent with both participants simultaneously looking at the facilitator, the same spot on the wall, or anything unrelated to the task). The proportion of time spent doing this negatively correlated with word length, lexical diversity, and syntactic complexity (all of which are markers of poor collaboration). Eye contact is positively associated with problem solving and facilitates conceptual understanding in group settings [24] so this result triangulates established literature findings. Joint visual attention being more focused on the maze and robot instead of the laptop (aoi_5) correlated positively with second person pronoun use and readability while negatively correlating with word length, word diversity, and use of the passive voice. This can be interpreted as dyads communicating with each other more effectively by looking at the physical problem space and talking through the steps needed to solve the problem versus spending more time in the programming interface editing code.

Two of our measures of synchrony (directional agreement for EDA and instantaneous derivative matching for motion) are positively associated with indices deemed good for collaboration and negatively correlated with indices seen to be negatively related to collaboration. By focusing on these four features from our multimodal data, we might be able to automatically assess collaboration during trials, which could be used to provide formative feedback and design new interventions based on these measurements.

Finally, we used supervised machine learning algorithms in hopes of being able to detect and intervene while dyads are working together. The relative feature importances from our Random Forest classifier also shed light on what indices are most useful for assessing collaboration. Second person pronoun incidence, number

of words, and lexical diversity appeared in our correlations with collaboration, while verb phrase density and the incidence of negations did not appear in our previous results. The emergence of negation in this model will need to be studied more thoroughly. Increased incidence of negation expressions may signal discord between the participants that could hinder the joint construction of meaning en route to problem solving. It is possible that the relationships between these features and collaboration are nonlinear and are thus not detected as readily by simple correlational analyses. Additionally, the overfitting of the models may be due to the lack of regularization of model complexity. With the range of -2 to 2 for the collaborative scoring, it might be more appropriate to fit a regression model instead of classifying the scores.

This preliminary work has several limitations that must temper the results. The small sample size of 40 groups leads to overfitting of our classifiers and may interfere with the ability of some of the Coh-Metrix algorithms to function. The designers recommend using a corpus of roughly 300 texts of 300 words each to study text easibility [3]. While the length of our transcripts exceeds these recommendations, it is unclear what effect our sample may have on this novel use of Coh-Metrix. We collected no reading level demographic data on our participants, nor did we ask for whom was English a first language. Additionally, this preliminary work does not address the important issue of how does communication (and thus collaboration) differ when participants have very different expressive language capabilities.

The developers of Coh-Metrix intended these indices to be the “low-hanging fruit” of computational linguistics, choosing to use simple metrics instead of complex computational linguistic models [3]. While this will likely be valuable for developing real-time dynamic interventions that can’t be slowed down by computationally expensive operations, we need to compare these results to more complex models and other natural language processing methods. Future work will also explore “driver-passenger” models that investigate emergent leadership behavior and uneven talk time in the discourse as well as the role of eye contact in the quality of collaboration.

7. CONCLUSION

This research paves the way for real-time detection of (un)productive interactions from multimodal data, potentially facilitating the development of fail-soft real-time interventions to support collaborative learning. While Coh-Metrix is only available currently as an online service, similar analytical platforms can be run locally [9] and could offer advice based on specific issues detected in the discourse rather than general distribution of talk time. These indices of cohesion and easibility have proven to be versatile and serve as effective features for estimating the rough quality of dyadic discourse with regard to collaboration quality.

ABSTRACT

Over the past decade, low graduation and retention rates have plagued higher education institutions. To help students graduate on time and achieve optimal learning outcomes, many institutions provide advising services supported by educational technologies. Accurate grade prediction is an integral part of these services such as degree planning software, personalized advising systems and early warning systems that can identify students at-risk of dropping from their field of study. In this work, we present next-term grade prediction models based on students' cumulative knowledge and co-taken courses. The proposed models are based on a matrix factorization framework and incorporate a co-taken course interaction function to learn the influence from the co-taken courses on the target course. The co-taken course interaction function is formed by a neural network, which takes the knowledge difference between the co-taken courses and the target course as input, and outputs an influence value that will be used to predict students' grades on the target course. The experimental results on various datasets from a U.S. University demonstrate that the proposed models significantly outperform competitive baselines across different test sets. Furthermore, we analyze the proposed models' performance with different numbers of co-taken courses as well as different numbers of co-taken course subjects, and highlight with an application case study how a student might make decisions related to selection of courses. The codes are available at <https://github.com/Zhiyun0411/EDM>.

knowledge, co-taken courses

1. INTRODUCTION

For over a decade higher education institutions in the United States have been grappling with low graduation rates [9]. The National Center for Education Statistics ¹ reports that approximately 59% of students who started college in 2009 were able to graduate and obtain a 4-year college program degree within 6 years. There is a pressing need for data-driven applications and services to guide students through academic pathways and achieve better learning outcomes. Many higher education institutions have implemented programs and services supported by educational technologies to increase overall graduation rates [17]. For example, Academic Advising service ² provides effective student-centered advising at Purdue University. Graduation Progression Success (GPS) Advising ³ implemented at Georgia State University helps identify at-risk students and have advisors respond alerts. Their reports show a 6% increase of 6-year graduation rate over 4 years. Our work aims to help students select courses for the next term by developing methods that can provide accurate grade prediction for the courses they have not taken yet.

In the past few years, many approaches have been developed for next-term grade prediction. One of the most popular approaches is matrix factorization (MF), which is inspired from the Recommender Systems (RS) literature [2, 3, 7, 15, 18]. Specifically, MF decomposes the student-course grade matrix into two matrices containing student and course latent factors, respectively. The predicted grade of a student on a course is given by the inner product of the corresponding student and course latent factors [4, 10]. There are other extended MF-based models which achieve better grade prediction results than MF. For example, Morsy *et al.* [8] proposed a Cumulative Knowledge-based Regression Model (CK) to tackle the next-term grade prediction problem. CK models each student with cumulative knowledge acquired by the student in the

CS262 is course “Low-level Programming”.

past terms. However, among all the existing methods for next-term grade prediction [2, 13, 14], very few consider the effect of co-taken courses on students’ performance.

We conduct a statistical analysis on a dataset collected from George Mason University in order to demonstrate the effects of co-taken courses on students’ performance. Figure 1 shows the true grade distribution of students’ on a specific course *with* and *without* enrolling in another course in the same term. The course pairs we choose in this analysis are frequently co-occurring in our dataset. For each target course pair, we choose the students who take more than four courses in a term, including the corresponding course pairs. We keep the students if the other co-taken courses only share few topics/material as the target course pairs. Figure 1 shows that students who take BIOL311 (Genetics) with CHEM313 (Organic Chemistry) have fewer “F”, “D” and “C” grades, and several more “B” grades than those students who only take BIOL311 in a term. Similar trend has been found for course pairs CS321 (Software Engineering) and ECE301 (Digital Electronics). Moreover, students who take MATH114 (Calculus) with CS211 (Object Oriented Programming) will have more “F” grades than those students who only take MATH114 in a term. Students who co-take MATH203 (Linear Algebra) and CS262 (Low-level programming) have more “C” grades than those students who only take MATH203 in a term. This shows that it can be challenging for students to take some courses together in a term (e.g., MATH114 and CS211, MATH203 and CS262), while it might not cause grade drop if taking other course pairs together (e.g., BIOL311 and CHEM313, CS321 and ECE301). Thus, we assume that co-taken courses can have substantial effect on student grades in different ways.

In this work, we propose grade prediction models that incorporate

both Cumulative Knowledge and Co-taken Courses (CKCC) to predict students’ performance in the next term. Inspired by Morsy *et al.* [8], the proposed methods model each student’s latent factors by cumulating the knowledge provided by the sequence of courses the student has taken in the past terms. Furthermore, we introduce a co-taken course interaction function to model the influence of the co-taken courses on students’ performance. The co-taken course interaction function is formed by a neural network which takes the knowledge difference between the co-taken courses and the target course as input, and outputs an influence value from the co-taken courses on the target course. We conduct comprehensive experiments on various datasets collected from George Mason University and thorough analysis on the effect of co-taken courses. Our experimental results show that CKCC significantly outperforms other competitive baselines methods for the task of grade prediction. We also provide detailed case study on how our model can help student in course selection for the next term.

The main contributions can be summarized as follows:

1. We develop CKCC models on next-term grade prediction. The models consider both students’ cumulative knowledge and co-taken courses in the target term. To the best of our knowledge, this is the first work that learns and explicitly incorporates influences from co-taken courses for grade prediction.
2. We provide a detailed case study on how our model helps students in course selection for the next term by comparing the performance of CKCC with different sets of co-taken courses.

2. RELATED WORK

2.1 Grade Prediction Approaches

Methods originating from recommender systems research have attracted increasing attention in educational data mining [2, 3, 13, 14, 20]. Sweeney *et al.* [18, 19] applied several recommender systems approaches to predict next-term grades. The authors implemented MF-based methods including SVD, SVD-kNN and factorization machine and simple baseline methods including global, student, and course means. The work showed that MF-based methods consistently achieve better grade prediction results over the baselines. Elbadrawy *et al.* [1] developed a domain-aware grade prediction method with student/course-group biases. This method groups students based on majors and academic levels. Additionally, it groups courses based on course levels and course subjects. The method assumes that the students/courses in a same group tend to have similar biases. Accordingly, this method models biases for each student and course group within a MF framework and achieved significant improvement on grade prediction performance over baselines.

2.2 Grade Prediction based on Student Historical Information

Polyzou *et al.* [12] addressed the future course grade prediction problem with different approaches based on sparse linear models and MF approaches. The experimental results showed that the course-specific regression approach achieved the best performance among all approaches. This method predict a student’s performance using a sparse linear combination of the grades that the student obtained in past courses. Morsy *et al.* [8] proposed a model named Cumulative Knowledge-based Regression Model (CK) to predict student’s grade on a certain course at the next term. CK

models each student with the cumulative knowledge he/she obtained from the sequence of courses he/she took in the past. Then CK calculated the inner product of the cumulative knowledge vector of a student and the required knowledge vector of the target course as the predicted grade. The experimental results showed that CK significantly outperforms MF in grade prediction. Ren *et al.* [13] proposed a matrix factorization model with temporal course-wise influence to predict next term student grades. This model considers two components in predicting a student's grade on a certain course: (i) the student's competence with respect to the target course's topics, content and requirements, etc., and (ii) student's previous performance over other courses. The study concluded that considering temporal influence can significantly improve the next-term grade prediction performance.

2.3 Neural Network in Educational Data Mining

Neural networks have been applied to solve many educational data mining problems. For example, Sharma *et al.* [16] proposed a composite deep neural network to predict whether the educational video is lively or not. The proposed method first used a convolutional neural network to extract the video features, and then used a deep recurrent neural network to predict the human movement label in order to detect video liveliness. Klingler *et al.* [6] presented a semi-supervised classification pipeline that employed deep variational auto-encoders to detect students who are suffering from developmental dyscalculia. Piech *et al.* [11] introduced Deep Knowledge Tracing (DKT) to model student learning with Recurrent Neural Networks. The authors provided experiments on how to use DKT to detect latent structure between the assessments in the dataset. The models proposed in this paper tackle the challenges of next-term grade prediction with students' history information (the sequence of courses the student has taken) and the co-taken courses in the next term. The main contribution of our model is to explicitly incorporate the co-taken courses with in MF framework.

3. PRELIMINARIES AND PROBLEM DEFINITION

3.1 Problem Definition

Formally, student-course grades will be represented by G_1, G_2, \dots, G_T for a total of T terms. Each G_t is a matrix, and contains the set of student-course grades for all students enrolled in courses within term t . For all the students, the set of student-course grades up to term t can be represented by $G^t = \bigcup_{i=1}^t G_i$. The set of courses that student s has taken in term t is represented by $C_{s,t}$ and the set of grades that student s achieves in term t is represented by $G_{s,t}$. The set of courses that student s has taken up to term t is represented by C_s^t , and the set of grades that student s has achieved up to term t is represented by G_s^t .

In this paper, all vectors are represented by bold lower-case letters and all matrices are represented by upper-case letters. Row vectors are represented by having the transpose superscript^T, otherwise by default they are column vectors. A predicted value is denoted by having a $\tilde{\cdot}$ symbol. Table 1 summarizes the key notations used in this paper.

Given student-course grades up to term $t - 1$ and the set of courses each student plans to take at term t , the objective of our work is to predict student's grades on a specific course given the set of co-taken courses at term t .

3.2 Grade Prediction based on Matrix Factorization

MF methods factor the student-course grade matrix into two matrices containing latent factors of courses and students in a common knowledge space, respectively [1, 12]. The dimension of the knowledge space is much lower than that of the original student-course grade matrix. We use \mathbf{p}_s ($\mathbf{p}_s \in \mathbb{R}^k$) and \mathbf{q}_c ($\mathbf{q}_c \in \mathbb{R}^k$) to represent latent factors of k dimensions for student s and course c , respectively. Thus, the grade of student s on course c can be predicted as

$$\tilde{g}_{s,c} = \mathbf{p}_s^T \mathbf{q}_c + b_s + b_c. \quad (1)$$

where b_s and b_c are bias terms for student s and course c , respectively.

3.3 Grade Prediction with Cumulative Knowledge

Morsy *et al.* [8] proposed the CK model which learns each student's latent factors with cumulative knowledge acquired by the student in past terms. Specifically, CK uses two vectors to model a course: the provided knowledge by the course and the prerequisite knowledge of the course, respectively. A student's latent factor is given by the knowledge accumulated from the previous course that the student has taken and the corresponding course grades. Formally, the cumulative knowledge acquired by student s up to term t is represented by $\mathbf{p}_{ck(s)}^t$, and is given by:

$$\mathbf{p}_{ck(s)}^t = \sum_{g_{s,c'} \in G_{s,t-1}} (e^{-\lambda(t-t_{s,c'})} \mathbf{k}_{c'} \cdot g_{s,c'}), \quad (2)$$

where $t_{s,c'}$ is the term in which student s took course c' , $e^{-\lambda(t-t_{s,c'})}$ is an exponential time decay function with $\lambda > 0$ denoting the decay rate, $\mathbf{k}_{c'}$ is the latent knowledge factor of course c' , and $g_{s,c'}$ is the grade of student s on course c' . Given $\mathbf{p}_{ck(s)}^t$, CK predicts student s 's grade on course c in term t as follows:

$$\tilde{g}_{s,c}^t = \mathbf{p}_{ck(s)}^t{}^T \mathbf{q}_c. \quad (3)$$

Note that in prior work, Ren *et al.* [14] have shown that CK can achieve better grade prediction performance when the cumulative knowledge $\mathbf{p}_{ck(s)}^t$ is averaged in Eq 3. Therefore, $\tilde{g}_{s,c}^t$ is presented as follows:

$$\tilde{g}_{s,c}^t = \frac{1}{|G_s^{t-1}|} \sum_{g_{s,c'} \in G_{s,t-1}} (e^{-\lambda(t-t_{s,c'})} \mathbf{k}_{c'} \cdot g_{s,c'})^T \mathbf{q}_c, \quad (4)$$

We refer to this model as the averaged cumulative knowledge (CK) model and will consider it as one of our baseline methods.

4. METHODS

4.1 Model Overview

In this paper, we propose grade prediction models that incorporate Cumulative Knowledge and Co-taken Courses (CKCC). To predict student s 's grade on course c in term t , CKCC takes into account two factors: i) cumulative knowledge of student s up to term $t - 1$, and ii) the other courses that will be taken together with course c in term t . To model the first factor, we adopt the CK model as in Eq. 4, that is, we cumulate the provided knowledge of the courses which student s has taken in the past, denoted as c' , to represent his/her cumulative knowledge, and use a latent factor to represent knowledge required by course c . To model the second factor, we introduce an co-taken course interaction function $f(\cdot)$ to learn the

Table 1: Notations

Notation	Explanation
m	number of courses
n	number of students
k	number of latent dimensions
$\mathbf{p}_{ck(s)}^t$	the cumulative knowledge of student s up to term t
\mathbf{q}_c	latent factor of the required knowledge components of course c
\mathbf{k}_c	latent factors of the provided knowledge components of course c
b_s	student bias term
b_c	course bias term
$g_{s,c}^t$	the grade of student s on course c at term t
$t_{s,c}$	the academic term when student s takes course c
G_t	student-course grades at term t
G^t	all the student-course grades up to term t
$G_{s,t}$	all the grades student s obtains at term t
G_s^t	all the grades student s obtains up to term t
$C_{s,t}$	the set of courses student s chooses at term t
C_s^t	the set of courses student s chooses up to term t

influence from co-taken courses, denoted as c'' , on student s 's grade on course c in term t .

Specifically, we use a latent vector \mathbf{q}_c to represent the knowledge components that course c requires. We hypothesize that the difference of the required knowledge between two courses will cause the influence from one course on the other, as shown in Figure 1. Based on this hypothesis, the difference between \mathbf{q}_c of course c and $\mathbf{q}_{c''}$ of a co-taken course c'' can be used in $f(\cdot)$ to learn the influence from c'' to c . We sum up the differences between each co-taken course c'' and c in order to aggregate the influence. Thus, the sum of the absolute values of the differences between each $\mathbf{q}_{c''}$ and \mathbf{q}_c , that is, $\sum_{c'' \in C_{s,t} \setminus \{c\}} |\mathbf{q}_{c''} - \mathbf{q}_c|$, is used in $f(\cdot)$ to learn the influence from all co-taken courses. Note that the use of absolute values here is to avoid the scenarios in which the influences from different co-taken courses are canceled out. Thus, CKCC predicts student s 's grade on course c in term t as follows:

$$\tilde{g}_{s,c}^t = \frac{1}{|G_{s,c}^{t-1}|} \sum_{g_{s,c'} \in G_{s,c}^{t-1}} (e^{-\lambda(t-t_{s,c'})} \mathbf{k}_{c'} \cdot g_{s,c'})^\top \mathbf{q}_c + f\left(\sum_{c'' \in C_{s,t} \setminus \{c\}} (|\mathbf{q}_{c''} - \mathbf{q}_c|)\right), \quad (5)$$

where $|\mathbf{q}_{c''} - \mathbf{q}_c|$ is the vector of absolute values of entry-wise difference between latent vector $\mathbf{q}_{c''}$ and latent vector \mathbf{q}_c , $c'' \in C_{s,t} \setminus \{c\}$ indicates that course c'' is one of courses taken together with c in term t . Note that in Eq. 5, the two terms share a common latent vector \mathbf{q}_c .

4.2 Co-taken Course Interaction Function

In CKCC, the co-taken course interaction function $f(\cdot)$ learns the influence on student s 's grade on course c from all the other co-taken courses in term t . We hypothesize that such influence can be nonlinear in general. Therefore, we use a feedforward neural network (FNN) [21] as $f(\cdot)$ to model the influence. The FNN takes the input as described in last section, and outputs a scalar influence value on course c . We use hyperbolic tangent (Tanh) as the activation function in each layer of the FNN. Note that when there are no hidden layers and no nonlinearity, the FNN model learns the weights directly from the input layer (i.e., difference of courses) to

```

the output layer (i.e., the influence), and the function $f(\cdot)$ becomes a simple inner product operation (parameterized by a vector). This simplified model is referred to as CKCC- I . Figure 2 shows the structure of the CKCC model.

4.3 Optimization of CKCC

Given the grade estimation as in Equation 5, we formulate the grade prediction problem for term T as the following optimization problem:

$$\begin{aligned} \underset{\Theta, \Theta_f}{\text{minimize}} \quad & \sum_s \sum_{t=1}^{T-1} \sum_{g_{s,c}^t \in G_s^t} (g_{s,c}^t - \tilde{g}_{s,c}^t)^2 \\ & + \alpha_1 (|\mathbf{k}_c| + |\mathbf{q}_c|) + \alpha_2 (\|\mathbf{k}_c\|_2^2 + \|\mathbf{q}_c\|_2^2) \\ & + \alpha_3 \|\text{vec}(\Theta_f)\|_2^2, \end{aligned} \quad (6)$$

where $\Theta = \{\{\mathbf{k}_c\}, \{\mathbf{q}_c\}\}$ represents the set of latent vectors, and Θ_f represents the parameters of $f(\cdot)$. α_1 , α_2 , and α_3 denote the nonnegative weights on the regularization terms to prevent overfitting.

The optimization process for CKCC is presented in Algorithm 1. It consists of two steps: The first step is to update the course parameters, i.e., Θ , using stochastic gradient descent. The second step is to update $f(\cdot)$ parameters, i.e., Θ_f , with the adaptive moment estimation (Adam) algorithm [5].

5. EXPERIMENTS

5.1 Dataset Description

The data used in this work is obtained from George Mason University. Our dataset contains two student groups: first-time freshmen (FTF; i.e., students who begin their study initially at this Uni-

versity), and transfer students (TR; i.e., students who transfer to this University from a different one). The dataset was extracted in the period of Fall 2009 to Spring 2018. It includes information of 23,435 FTF students and 28,470 TR students across 153 majors. For simplicity, we use students from six different majors to evaluate the proposed models. These majors have different numbers of enrolled students, courses, and different major syllabi. We will evaluate these majors on both FTF and TR student groups. The majors in our experiment include: (i) Mathematical Sciences (MATH), (ii) Physics (PHYS), (iii) Chemistry (CHEM), (iv) Information Technology (IT), (v) Computer Science (CS) and (vi) Biology (BIOL). Table 2 shows the statistics across these majors.

5.2 Experimental Protocols

To assess the performance of our next-term grade prediction models, we trained our models on data up to term $T-1$ and make predictions for term T . We evaluate our method for three test terms, i.e., Spring 2018, Fall 2017 and Spring 2017. As an example, for evaluating predictions for term Fall 2017, data from Fall 2009 to Spring 2017 is considered as training data and data from Fall 2017 is testing data. datasets. Figure 3 shows the three different train-test splits.

Figure 3: Different Experimental Protocols

5.3 Evaluation Metrics

In our experiments, we use Mean Absolute Error (MAE) to evaluate the predicted results in numbers. MAE is calculated as:

$$MAE = \frac{\sum_{g_{s,c}^t \in G_T} |g_{s,c}^t - \tilde{g}_{s,c}^t|}{|G_T|} \quad (7)$$

where $g_{s,c}^t$ and $\tilde{g}_{s,c}^t$ are the ground-truth grade and predicted grade for student s on course c at term T , respectively. G_T is the set of student-course grades in the T -th term, which is considered as the test set in our experiment.

Moreover, since a student receives a letter grade for a course, i.e., A, A-, ..., F, we use the Percentage of Tick Accuracy (PTA) [12] as one of our evaluation metrics. During training, we map letter grades "A+" and "A" to the real-valued grade point number 4.0, "A-" to 3.67, "B+" to 3.33, etc. During testing, we map the predicted grade point numbers back to their closest letter grades. Then, we define tick as the difference between two consecutive letter grades (e.g., C+ vs C or C vs C-). We then compute the percentage of predicted grades that match the actual grades (or within 0-ticks of them), and those that are within 1 tick and within 2 ticks of the actual grades as PTA_0 , PTA_1 , and PTA_2 , respectively.

5.4 Compared Methods

Since there is no prior research on the influence of co-taken courses within a same term, we use the two following methods and three other variants of CKCC as baselines in our experiments:

- **MF** The MF model is described as Eq. 1.
- **CK** The CK model is described as Eq. 4.
- **MFCC** We add the co-taken course influence to the MF model, and obtain the Matrix Factorization with Co-taken Courses (MFCC) model. Specifically, the predicted grade of student s on course c at term t is defined as

$$\hat{g}_{s,c}^t = \mathbf{p}_s^T \mathbf{q}_c + f\left(\sum_{c'' \in C_s^t \setminus c} (|\mathbf{q}_{c''} - \mathbf{q}_c|)\right), \quad (8)$$

where \mathbf{p}_s denotes the latent factors of for student s . Similar to the CKCC model, we optimize the MFCC model with two steps by alternately updating the latent factors and the model parameters in the mapping function $f(\cdot)$.

- **MFCC- l** The MFCC- l model is a special case of the MFCC model where $f(\cdot)$ is simply an inner product (parameterized by a vector) instead of an FNN.
- **CKCC- l** The CKCC- l model is described in Section 4.2.

5.5 Parameter Learning

The set of parameters in the optimization problem (Eq 6) includes the number of latent dimensions (i.e., k), regularization parameters (i.e., α_1 , α_2 , and α_3) and the decay rate (i.e., λ). We performed a grid search over all the parameters with $k \in \{5, 10, \dots, 25\}$, and $\alpha_1, \alpha_2, \alpha_3, \lambda \in \{1e-3, 1e-2, 0.1\}$. Note that for the CKCC and MFCC models, the optimal neural network structure (e.g., number of layers, the size of each layer) depends on the value of k . Thus, we swept different neural network structure parameters for every k value in our grid search. The neural network structures that consistently achieve good performance contain one hidden layer with 2 or 3 hidden units.

6. RESULTS AND DISCUSSION

6.1 Overall Performance

Table 3 and 4 shows the overall performance for all methods for both FTF and TR student groups, respectively.

Table 3 shows that for FTF students, CKCC and CKCC- l outperform the baseline methods over most datasets. Specifically, CKCC outperforms the other compared methods across different experimental protocols by 4.39%, 7.01%, 3.50%, 3.87% in terms of MAE, PTA₀, PTA₁, and PTA₂, respectively. Furthermore, CK based methods outperform MF based methods on all experimental protocols. This table also shows that co-taken course based methods (MFCC, MFCC- l and CKCC, CKCC- l) outperform their baseline methods (MF and CK) on all experimental protocols, respectively. This illustrates that for FTF students, both cumulative knowledge and co-taken courses have great influence on student's performance, and the proposed methods can capture such influence accurately.

Table 4 shows that CK has competitive results over TR students. Moreover, for MF based methods, MFCC and MFCC- l outperform MF for all the experimental protocols. This illustrates that co-taken courses are likely to have influence on student's performance, but

the influence may not be as strong as it is of cumulative knowledge for TR students.

6.2 Analysis on Individual Majors

In order to understand the proposed methods' performance on each major, we have tested all the aforementioned methods on different majors separately. We conducted this group of experiments for both FTF and TR students. And we use Spring 2018 as test set. We provide detailed experimental results in Table 5 and 6.

Table 5 shows that the CKCC model outperforms other compared methods for some majors (e.g., PHYS, CS) on all metrics, but has weak performance on some metrics for other majors (e.g., MATH, CHEM). Especially for MATH major, CKCC has the highest MAE result while MFCC and MFCC- l have the best MAE result. The reason might be that the performance of CKCC relies on the student historical information, and it tends to have good performance on the students with rich historical information. However, in the test set, some students in certain majors do not have much historical information and thus drag down the model performance. Table 6 shows that, for TR students, there is no method that consistently outperforms others across different metrics. The reason might be that the diversity in student characteristics (many TR students have different backgrounds) leads to diverse course selection plans among them. Such diversity greatly influences the performance of the different models.

6.3 Linear versus Nonlinear Mapping Function

As aforementioned, we have two forms of co-taken course interaction function: FNN model and linear model (parameterized by a vector). Specifically, we compare the results for MFCC versus MFCC- l , and CKCC versus CKCC- l , respectively, in order to understand how different mapping functions $f(\cdot)$ influence grade prediction performance. Table 3 shows that for FTF students, MFCC- l has slightly better performance than MFCC, and CKCC- l has competitive performance as CKCC across different experimental protocols. Same trend has shown in table 4 for TR students. Furthermore, table 5 shows that MFCC and CKCC consistently outperform MFCC- l and CKCC- l across different majors for FTF students. This illustrates that the influence of co-taken courses for FTF student group can be better captured by a nonlinear model (i.e., FNN) than a simple linear model. Table 6 shows that for TR students, MFCC and CKCC don't always outperform MFCC- l and CKCC- l for different majors. The reason might be that some TR students will have fewer co-taken courses than those of FTF students, and the influence from co-taken courses can be well captured by a linear model.

6.4 Performance on Different Numbers of Co-taken Courses

In this section, we test the CKCC model on different data subgroups with different number of co-taken courses in a term. Specifically, we take the students in the test set and divide them into five groups: students who take $\{2, 3, 4, 5, 6+\}$ courses (6+ refers to six and more). We perform this experiment on each major for both FTF and TR students, respectively. For the sake of page limit, we only show the results for FTF students. Figure 4 shows the experimental results in terms of PTA₀, PTA₁ and PTA₂. The results show that different majors exhibit different trends when the number of co-taken courses varies. For example, for CHEM and BIOL majors, the performance of the CKCC model on PTA improves with more

Figure 4: PTA Results for Different Number of Co-taken Courses on FTF students

Figure 5: PTA Results for Different Number of Co-taken Course Subjects on FTF students

co-taken courses. This observation suggests that CKCC is able to leverage stronger influence of co-taken courses to improve its performance. However, for PHYS and CS majors, CKCC achieves better performance with 2, 3 or 6+ co-taken courses than with 4 or 5 co-taken courses. We postulate that this is due to the characteristics of courses chosen within a term and their content. These results also indicate that CKCC is able to model co-taken courses' influence despite of the number of the co-taken courses.

6.5 Performance on Different Numbers of Co-taken Course Subjects

In this section, we extract each course's subject and test the CKCC model on different data subgroups with different number of co-taken course subjects in a term. The reason we conduct this experiment is because we assume that courses with the same subject tend to have relevant knowledge components. Students who have co-taken courses from many different subjects may have wide knowledge diversity. This experiment aims to test the performance of CKCC in terms of co-taken course subjects.

Specifically, we take the students in the test set and divide them into five groups: students who take courses from $\{1, 2, 3, 4, 5\}$ subjects in a term. Since there are few students co-taking courses from 6+ subjects, we exclude these students in our experiment. We perform this group of experiment on each major for both FTF and TR students, respectively. For the sake of page limit, we only show the results for FTF students. Figure 5 shows the experimental results in terms of PTA_0 , PTA_1 and PTA_2 . The results show that CKCC have different prediction results regarding the number of co-taken course subjects for different majors. For example, for CHEM, CS and BIOL majors, the performance of the CKCC model on PTA has the best performance with 1 co-taken course subject than other

subgroups. This observation suggests that CKCC is able to model co-taken courses' influence better with less knowledge diversity in a term. However, for IT major, CKCC achieves better performance with more co-taken course subjects. And for MATH and PHYS majors, CKCC has better performance on 2 or 5 co-taken course subjects than other subgroups. We assume that this is affected by the characteristics of different majors. Moreover, for MATH and IT major, the PTA results don't vary much comparing to CHEM and BIOL majors. This illustrates that for some majors, students may take courses from several subjects at a term, and the CKCC model can still well capture the co-taken courses' influence.

7. SIGNIFICANCE AND IMPACT

To highlight the use-case scenario of the developed next term grade prediction approach using co-taken courses, we ran a simulated case study. Having demonstrated the prediction accuracy of these proposed models, the objective of this case study is to highlight the strengths of the proposed models in helping students to select courses in the future term. Implicitly we want to provide students information about their workload (or change in their overall grades) by addition of one or more courses within the next term.

Specifically, we extract two pairs of popular co-taken courses: BIOL311 ("General Genetics") and CHEM313 ("Organic Chemistry"), MATH213 ("Analytic Geometry and Calculus II") and PHYS260 ("University Physics"), and conduct a study to illustrate how our model can help plan students' course selections or allocate the necessary study time. Take the course pair BIOL311 and CHEM313 as an example. We extract the students who take course BIOL311 and CHEM313 together in a term. We predict students' performance on course BIOL311 using the CKCC model. We then eliminate course CHEM313 from our data set and predict the grade on course BIOL311 again using the CKCC model. Comparing the

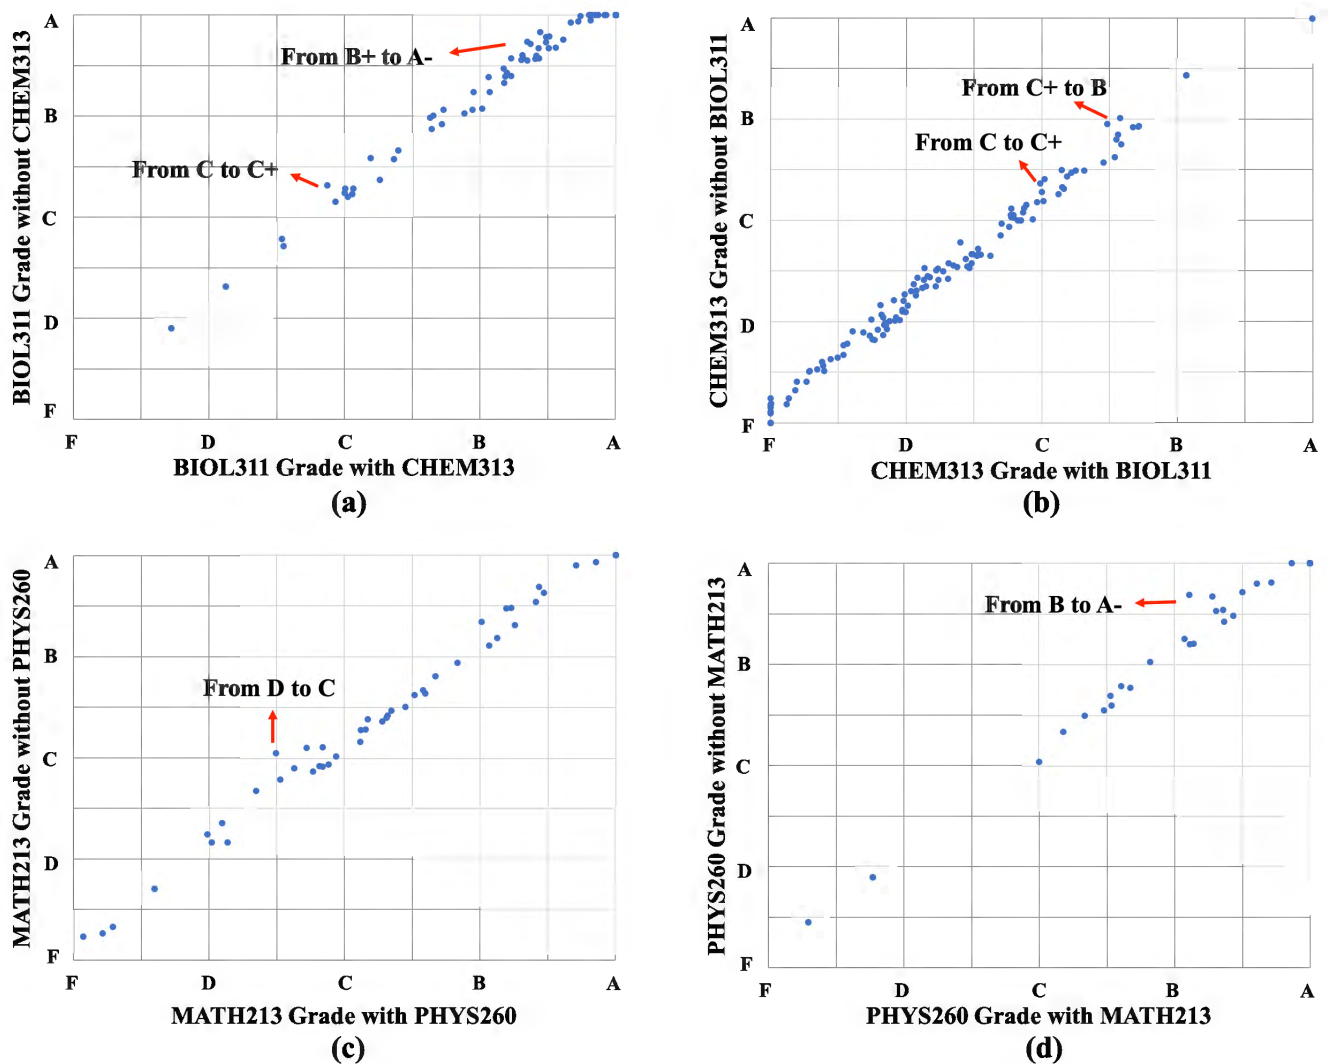

Figure 6: Comparison Results on the Co-taken Course Influence

predicted grades helps determine if the two courses should be taken together within the same term or not. The sampled students have a total of five courses that they are enrolled in for the particular term. The comparison results are shown in Figure 6 (a). It is a scatter plot of predicted grades for a student where the x-axis shows the performance on course BIOL311 co-taken with the CHEM313 and the y-axis is the performance on course BIOL311 with course CHEM313 removed. We have conducted the same experiments for other course pairs using the same protocol and shown these results in Figure 6 (b), (c) and (d).

In general, students' performance will get better with the other course eliminated due to the reduction in workload. However, different students get affected differently by the additional course. For students who take BIOL311 and CHEM313, some of them will have improvement in BIOL311 grades if they do not enroll for CHEM313 in the same semester. On the other hand, some students will not have any change in their grades for BIOL311 based on course CHEM313 (the plotted results along the diagonal). Similar trends can be observed in Figure 6 (b), (c) and (d) as well. In

the Figure 6, we also highlight different cases where students grade changes with the removal of the particular course. Using this information, students can plan the set of courses that they might enroll for in the next term, and allocate study time accordingly.

8. CONCLUSION AND FUTURE WORK

In this work, we propose grade prediction models that incorporate both cumulative knowledge and co-taken courses (CKCC) to predict students' performance in the next term. The proposed models consider both cumulative knowledge a student has acquired after taking a series of courses in the passing terms, and the co-taken courses the student plans to take in the next term. Our experimental results on a dataset from George Mason University shows that the proposed models significantly outperform other competitive baselines over most the datasets for the task of next-term grade prediction. Moreover, our experimental results show that the proposed model is able to capture strong influence of co-taken courses to improve its grade prediction performance. Furthermore, we ran a simulated case study to illustrate how our proposed model can help students in course selection for the future term.

In the future, we plan to take into account additive factors, such as instructor, student's academic level and course's difficulty level along with co-taken course information, in order to achieve more accurate grade prediction results. We hope such a grade prediction system can not only help students select courses, finish their study at college but also guide them in career planning in the future.

ABSTRACT

Deep Reinforcement Learning (DRL) has been shown to be a very powerful technique in recent years on a wide range of applications. Much of the prior DRL work took the *online* learning approach. However, given the challenges of building accurate simulations for modeling student learning, we investigated applying DRL to induce a pedagogical policy through an *offline* approach. In this work, we explored the effectiveness of offline DRL for pedagogical policy induction in an Intelligent Tutoring System. Generally speaking, when applying offline DRL, we face two major challenges: one is limited training data and the other is the credit assignment problem caused by delayed rewards. In this work, we used Gaussian Processes to solve the credit assignment problem by estimating the inferred immediate rewards from the final delayed rewards. We then applied the DQN and Double-DQN algorithms to induce adaptive pedagogical strategies tailored to individual students. Our empirical results show that without solving the credit assignment problem, the DQN policy, although better than Double-DQN, was no better than a random policy. However, when combining DQN with the inferred rewards, our best DQN policy can outperform the random yet reasonable policy, especially for students with high pre-test scores.

1. INTRODUCTION

Interactive e-Learning Environments such as Intelligent Tutoring Systems (ITSs) and educational games have become increasingly prevalent in educational settings. In order to design effective interactive learning environments, developers must form the basic core of the system and determine *what* is to be taught and *how*. *Pedagogical strategies* are policies that are used to decide the *how* part, what action to take next in the face of alternatives. Each of these systems' decisions will affect the user's subsequent actions and performance.

Reinforcement Learning (RL) is one of the best machine learning approaches for decision making in interactive envi-

ronments and RL algorithms are designed to induce effective policies that determine the best action for an agent to take in any given situation to maximize some predefined cumulative reward. In recent years, deep neural networks have enabled significant progress in RL research. For example, Deep Q-Networks (DQNs) [26] have successfully learned to play Atari games at or exceeding human level performance by combining deep convolutional neural networks and Q-learning. Since then, DRL has achieved notable successes in a variety of complex tasks such as robotics control [1] and the game of Go [44]. From DQN, various DRL methods such as Double DQN [51] or Actor-Critic methods [38, 39] were proposed and shown to be more effective than the classic DQN. Despite DRL's great success, there are still many challenges preventing DRL from being applied more broadly in practice, including applying it to educational systems. One major problem is sample inefficiency of current DRL algorithms. For example, it takes DQN hundreds of millions of interactions with the environment to learn a good policy and generalize to unseen states, while we seek to learn policies from datasets with fewer than 800 student-tutor interaction logs.

Generally speaking, there are two major categories of RL: online and offline. Online RL algorithms learn policy while the agent interacts with the environment; offline RL algorithms, by contrast, learn the policy from pre-collected training data. Online RL methods are generally appropriate for domains where the state representation is clear and interacting with simulations and actual environments is relatively computationally cheap and feasible, so most of prior work on DRL mainly took an online learning approach. On the other hand, for domains such as e-learning, building accurate simulations or simulating students is especially challenging because human learning is a rather complex, not fully understood process; moreover, learning policies while interacting with students may not be feasible and more importantly, may not be ethical. Therefore, our DRL approach is offline. This approach was achieved by, first, collecting a training corpus. One common convention, and the one used in our study, is to collect an *exploratory* corpus by training a group of students on an ITS that makes random yet *reasonable* decisions and then apply RL to induce pedagogical policies from that exploratory training corpus. An empirical study was then conducted from a new group of human subjects interacting with different versions of the system. The only difference among the versions was the policy employed by the ITS. Lastly, the students' performance was statistically

Markel Sanz Ausin, Hamoon Azizsoltani, Tiffany Barnes and Min Chi "Leveraging Deep Reinforcement Learning for Pedagogical Policy Induction in an Intelligent Tutoring System" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 168 - 177

compared. Due to cost limitations, typically, only the *best* RL-induced policy was deployed and compared against some baseline policies.

When applying offline DRL to ITSs, we often face one major challenge: our rewards are often not only noisy but also delayed. Given the nature of ITS data collection, the training data including our reward functions is often noisy and our rewards are only the incomplete or imperfect observations of underlying true reward mechanisms. Due to the complex nature of student learning, the most appropriate rewards are (delayed) student learning gains, which are only available after the entire training is complete. For example, hints might improve immediate performance but negatively impact overall learning. On the other hand, when the size of the training data is limited, the availability of “true” immediate rewards is very important for offline RL. Immediate rewards are generally more effective than delayed rewards for offline RL because it is easier to assign appropriate credit or blame when the feedback is tied to a single decision. The more we delay rewards or punishments, the harder it becomes to assign credit or blame properly. Therefore, the challenge is how to distribute the delayed rewards to observable, immediate rewards along each student-system interactive trajectory while taking the noise and uncertainty in the data into account. To tackle this issue, we applied a Gaussian Processes based (GP-based) approach to infer “immediate rewards” from the delayed rewards and then applied DQN to induce two policies: one based on delayed rewards and the other based on the inferred immediate rewards, referred to as DQN-Del and DQN-Inf respectively.

In this work, we used a logic ITS and focused on applying DRL to induce a policy on one type of tutorial decision: whether to present a given problem as a *problem solving* (PS) or a *worked example* (WE). The tutor presents a worked example (WE) by demonstrating the individual steps in an expert solution to a problem. During PS, students are required to complete the problem with tutor support (e.g. hints). The effectiveness of DQN-Del and DQN-Inf are evaluated theoretically using Expected Cumulative Reward (ECR) and empirically through two randomly controlled experiments: one for evaluating the effectiveness of DQN-Del in Spring 2018 and the other for evaluating DQN-Inf in Fall 2018. In each experiment, the effectiveness of the corresponding RL-induced policy was compared against the *Random* policy that flips a coin to decide between WE/PS and the students were randomly assigned into the two conditions while balancing their incoming competence. Overall, the results from both experiments showed no significant difference between the DQN-Del and Random in Spring 2018 and between the DQN-Inf and Random in Fall 2018 on every measure of learning performance.

There are two potential explanations for such findings. First, our random baseline policy is decently strong. While random policies are usually bad in many RL tasks, in the context of WE vs. PS, our random policies can be strong baselines. Indeed, some learning literature suggests that the best instructional intervention is to alternate WE and PS [35, 41, 36]. Second, there may be an **aptitude-treatment interaction** (ATI) effect [6, 47], where certain students are less sensitive to the induced policies, meaning they achieve a

similar learning performance regardless of policies employed; whereas other students are more sensitive, meaning their learning is highly dependent on the effectiveness of the policies. Thus, we divided the students into High vs. Low based on their incoming competence and investigated the ATI effect. While no ATI effect was found between DQN-Del and Random for Spring 2018, a significant ATI effect was found between DQN-Inf and Random in Fall 2018.

In short, we explored applying offline DRL for pedagogical policy induction based on delayed and inferred immediate rewards. Our results showed that no ATI effect was found between DQN-Del and Random in Spring 2018, whereas there was an ATI effect between DQN-Inf and Random in Fall 2018. More specifically, the High incoming competence group benefited significantly more from the DQN-Inf policy than their peers in the Random condition. This result suggests that the availability of inferred immediate rewards was crucial for effectively applying offline DRL for pedagogical policy induction.

2. BACKGROUND

A great deal of research has investigated the differing impacts of worked examples (WE) and problem solving (PS) on student learning [49, 22, 21, 23, 41, 27, 36]. McLaren and colleagues compared WE-PS pairs with PS-only [22]. Every student was given a total of 10 training problems. Students in the PS-only condition were required to solve every problem while students in the WE-PS condition were given 5 example-problem pairs. Each pair consisted of an initial worked example problem followed by tutored problem solving. They found no significant difference in learning performance between the two conditions. However, the WE-PS group spent significantly less time than the PS group.

McLaren and his colleagues found similar results in two subsequent studies [21, 23]. In the former, the authors compared three conditions: WE, PS and WE-PS pairs, in the domain of high school chemistry. All students were given 10 identical problems. As before, the authors found no significant differences among the three groups in terms of learning gains but the WE group spent significantly less time than the other two conditions; and no significant time on task difference was found between the PS and WE-PS conditions.

In a follow-up study, conducted in the domain of high school stoichiometry, McLaren and colleagues compared four conditions: WE, tutored PS, untutored PS, and Erroneous Examples (EE) [23]. Students in the EE condition were given *incorrect* worked examples containing between 1 and 4 errors and were tasked with correcting them. The authors found no significant differences among the conditions in terms of learning gains, and as before the WE students spent significantly less time than the other groups. More specifically, for time on task, they found that: $WE < EE < untutored PS < tutored PS$. In fact, the WE students spent only 30% of the total time that the tutored PS students spent.

The advantages of WEs were also demonstrated in another study in the domain of electrical circuits [50]. The authors of that study compared four conditions: WE, WE-PS pairs, PS-WE pairs (problem-solving followed by an example problem), and PS only. They found that the WE and WE-PS

students significantly outperformed the other two groups, and no significant differences were found among four conditions in terms of time on task.

In short, prior research has shown that WE can be similar or more effective than PS or alternating PS with WE, and the former can take significantly less time than the latter two [49, 22, 21, 23, 41]. However, there is no widespread consensus on how or when WE vs. PS should be used. This is why we will derive pedagogical strategies for them directly from empirical data.

2.1 ATI Effect

Previous work shows that the ATI effect commonly exists in many real-world studies. More formally, the ATI effect states that instructional treatments are more or less effective to individual learners depending on their abilities [6]. For example, Kalyuga et al. [17] empirically evaluated the effectiveness of worked example (WE) vs. problem solving (PS) on student learning in programmable logic. Their results show that WE is more effective for inexperienced students while PS is more effective for experienced learners.

Moreover, D’Mello et al. [7] compared two versions of ITSs: one is an affect-sensitive tutor which selects the next problem based on students’ affective and cognitive states combined, while the other is an original tutor which selects the next problem based on students’ cognitive states alone. An empirical study shows that there is no significant difference between the two tutors for students with high prior knowledge. However, there is a significant difference for students with low prior knowledge: those who trained on the affect-sensitive tutor had significantly higher learning gain than their peers using the original tutor.

Chi and VanLehn [4] investigated the ATI effect in the domain of probability and physics, and their results showed that high competence students can learn regardless of instructional interventions, while for students with low competence, those who follow the effective instructional interventions learned significantly more than those who did not. Shen and Chi [43] find that for pedagogical decisions on WE vs. PS, certain learners are always less sensitive in that their learning is not affected, while others are more sensitive to variations in different policies. In their study, they divided students into Fast and Slow groups based on time, and found that the Slow groups are more sensitive to the pedagogical decisions while the Fast groups are less sensitive.

3. RELATED WORK

Deep Reinforcement Learning: In recent years, many DRL algorithms have been developed for various applications such as board games like Go [44, 46], Chess and Shogi [45], robotic hand dexterity [33, 1], physics simulators [19, 29, 30], and so forth. While most DRL algorithms have been mainly applied online, some of them can also be applied offline. More specifically, DRL algorithms such as Vanilla Policy Gradient (VPG) [48], Proximal Policy Optimization (PPO) [39], Trust Region Policy Optimization (TRPO) [38], or A3C [24] can only be applied for online learning by interacting with simulations. Some other DRL algorithms can be applied for offline learning using pre-collected training data. These include the Q-learning based approaches such as Deep

Q-Network (DQN) [26], Double-DQN [51], prioritized experience replay [37], distributed prioritized experience replay (Ape-X DQN) [14], and the Actor-Critic based methods such as Deep Deterministic Policy Gradient (DDPG) [19], Twin Delayed Deep Deterministic policy gradient (TD3) [9], or Soft Actor-Critic (SAC) [11]. Among them, DQN and its variants have been much more extensively studied, however, it is still not clear whether they can be successfully applied *offline* for pedagogical policy induction for ITSs.

Reinforcement Learning in Education: Prior research using online RL to induce pedagogical policies has often relied on simulations or simulated students, and the success of RL is often heavily dependent on the accuracy of the simulations. Beck et al. [3] applied temporal difference learning, with off-policy ϵ -greedy exploration, to induce pedagogical policies that would minimize student time on task. Iglesias et al. applied another common online approach named Q-learning to induce policies for efficient learning [15, 16]. More recently, Rafferty et al. applied POMDP with tree search to induce policies for faster learning [32]. Wang et al. applied an online Deep-RL approach to induce a policy for adaptive narrative generation in educational game [52]. All of the models described above were evaluated by comparing the induced policy with some baseline policies via simulations or classroom studies.

Offline RL approaches, on the other hand, “take advantage of previously collected samples, and generally provide robust convergence guarantees” [40]. Shen et al. applied value iteration and least square policy iteration on a pre-collected training corpus to induce pedagogical policies for improving students’ learning performance [43, 42]. Chi et al. applied policy iteration to induce a pedagogical policy aimed at improving students’ learning gains [5]. Mandel et al. [20] applied an offline POMDP approach to induce a policy which aims to improve student performance in an educational game. In classroom studies, most models above were found to yield certain improved student learning relative to a baseline policy.

DRL in Education is a subject of growing interest. DRL adds deep neural networks to RL frameworks such as POMDP for function approximation or state approximation [25, 26]. This enhancement makes the agent capable of achieving complicated tasks. Wang et al. [52] applied a DRL framework for personalizing interactive narratives in an educational game called CRYSTAL ISLAND. They designed the immediate rewards based on normalized learning gain (NLG) and found that the students with the DRL policy achieved a higher NLG score than those following the linear RL model in *simulation* studies. Furthermore, Narasimhan et al. [28] implemented a Deep Q-Network (DQN) approach in text-based strategy games, constructed based on Evennia, which is an open-source library and toolkit for building multi-users online text-based games. Using simulations, they found that the DRL policy significantly outperformed the random policy in terms of quest completion.

In summary, compared with MDP and POMDP, relatively little research has been done on successfully applying DRL to the field of ITS. None of the prior research has successfully applied DRL to ITSs without simulated environments,

in order to learn an effective pedagogical strategy that makes students learn in a more efficient manner. Furthermore, no prior work has empirically evaluated any DRL-induced policy to confirm its benefits on real students.

4. METHODS

In RL, the agent interacts with an environment \mathcal{E} , and the goal of the agent is to learn a policy that will maximize the sum of future discounted rewards (also known as the return) along the trajectories, where each trajectory is one run through the environment, starting in an initial state and ending in a final state. This is done by learning which action to take for each possible state. In our case, \mathcal{E} is the learning context, and the agent must learn to take the actions that lead to the optimal student learning, by maximizing the return $R = \sum_{t=0}^T \gamma^t r_t$, where r_t is the reward at time step t , T is the time step that indicates the end of the trajectory, and $\gamma \in (0, 1]$ is the discount factor.

4.1 DQN and Double-DQN

Deep Q-Network (DQN) is, fundamentally, a version of Q-learning. In Q-learning, the goal is to learn the optimal action-value function, $Q^*(s, a)$, which is defined as the expected reward obtained when taking the optimal action a in state s , and following the optimal policy π^* until the end of the trajectory. For any state-action pair, the optimal action-value function must follow the Bellman optimality equation in that:

$$Q^*(s, a) = r + \gamma \max_{a'} Q^*(s', a') \quad (1)$$

Here r is the expected immediate reward for taking action a at state s ; γ is the discount factor; and $Q^*(s', a')$ is the optimal action-value function for taking action a' at the subsequent state s' and following policy π^* thereafter.

Compared with the original Q-learning, DQNs use neural networks (NNs) to approximate action-value functions. This is because NNs are great universal function approximators and they are able to handle continuous values in both their inputs and outputs. In order to train the DQN algorithm, two neural networks with equal architectures are employed. One is the main network and its weights are denoted θ and the other is the target network, and its weights are denoted θ^- . The target value used to train the network is $y := r + \gamma \max_{a'} Q(s', a'; \theta^-)$. Thus, the loss function that is minimized in order to train the main network is:

$$Loss(\theta) = \mathbb{E}[(y - Q(s, a; \theta))^2] \quad (2)$$

The main network is trained on every training iteration, while the target network is frozen for a number of training iterations. Every m training iterations, the weights of the main neural network are copied into the target network. This is one of the techniques used in order to avoid divergence during the training process. Another one of these techniques was the use of an experience replay buffer. This buffer contains the p most recent (s, a, r) tuples, and the algorithm randomly samples from the buffer when creating the batch on each training iteration. We followed the same procedure, but as our training was performed offline, the experience replay buffer consists of all the samples on our training corpus, and it does not get refreshed over time.

Double-DQN or DDQN was proposed by Van Hasselt et al. [12] who combined it with neural networks in the Double-DQN algorithm [51]. The intuition behind it is to decouple the action selection from the action evaluation. To achieve this, the Double-DQN algorithm uses the main neural network to first select the action that has the highest Q-value for the next state ($\arg\max_{a'} Q(s', a'; \theta)$) and then evaluates the Q-value of the selected action using the target network ($Q(s', \arg\max_{a'} Q(s', a'; \theta); \theta^-)$). This simple trick has been proven to significantly reduce overestimations in Q-value calculations, resulting in better final policies. With this technique, the target value used to optimize the main network becomes:

$$y := r + \gamma Q(s', \arg\max_{a'} Q(s', a'; \theta); \theta^-) \quad (3)$$

The loss function is still the same as in equation 2, but the target value y used in the formula is now updated to be the one in equation 3.

4.2 Fully Connected vs. LSTM

For our NN architectures, we explored two options: Fully connected NNs and Long Short Term Memory (LSTM).

Fully Connected or multi-layer perceptrons are the simplest form of neural network units. They calculate a simple weighted sum of all the input units, and each unit produces an output value that is often passed to an activation function. We used these units to parametrize our neural networks. All the input units are connected to all the units in the first hidden layer, and all those units are connected to every unit in the next hidden layer. This process continues until the final output layer.

Figure 1: A single LSTM unit containing a forget, input and output gate

Long Short-Term Memory (LSTM) is a type of recurrent neural network specifically designed to avoid the vanishing and exploding gradient problems [13]. LSTMs are particularly suitable for tasks where long-term temporal dependencies must be remembered. They achieve this by maintaining the previous information of hidden states as internal memory. Figure 1 shows the architecture of a single LSTM unit. It consists of a memory cell state denoted by C_t and three gates: the forget gate $f_t \in [0, 1]$, the input gate $i_t \in [0, 1]$, and the output gate $o_t \in [0, 1]$. These three gates interact with each other to control the flow of information. During training, the network learns what to memorize and when to allow writing to the cell in order to minimize the

training error. More specifically, the forget gate determines what information from the previous memory cell state is expired and should be removed; the input gate selects information from the *candidate* memory cell state C_t^* to update the cell state; and the output gate filters the information from the memory cell so that the model only considers information relevant to the prediction task. The value of each gate is computed as follows, where $W_{[i,f,C,o]}$ are the weight matrices and $b_{[i,f,C,o]}$ are the bias vectors:

$$\begin{aligned} i_t &= \text{sigmoid}(W_i \cdot [y_{t-1}, X_t] + b_i) \\ f_t &= \text{sigmoid}(W_f \cdot [y_{t-1}, X_t] + b_f) \\ C_t^* &= \tanh(W_C \cdot [y_{t-1}, X_t] + b_c) \\ o_t &= \text{sigmoid}(W_o \cdot [y_{t-1}, X_t] + b_o) \end{aligned} \quad (4)$$

The memory cell value C_t and output value y_t from the LSTM unit are computed using the following formulas:

$$\begin{aligned} C_t &= C_{t-1} \cdot f_t + C_t^* \cdot i_t \\ y_t &= o_t * \tanh(C_t) \end{aligned} \quad (5)$$

4.3 Inferring Immediate Rewards

A historical dataset \mathcal{H} consists of m trajectories, h_1 to h_m and n unknown immediate rewards. We would like to infer the immediate rewards given delayed rewards. In order to infer the immediate rewards, we used a minimum mean square error (MMSE) estimator in the Bayesian setting [18, 8, 10]. Assume $\mathbf{R} = \mathbf{D}\mathbf{r} + \varepsilon$ is a linear process where \mathbf{D} is a known matrix, \mathbf{r} is a $n \times 1$ random vector of unknown immediate rewards, \mathbf{R} is a $m \times 1$ vector of observed delayed rewards and ε is a vector of independent and identically distributed noise with mean of zero and standard deviation of $\sigma_{\mathbf{R}}$. Assuming the discounted sum of the immediate rewards is equal to the delayed rewards, a linear model matrix \mathbf{D} is proposed as:

$$\mathbf{D} = \begin{bmatrix} \overbrace{1 \quad \gamma \quad \gamma^2 \quad \dots}^{h_1} & \overbrace{0 \quad 1 \quad \gamma \quad \gamma^2 \quad \dots}^{h_2} & \dots & 0 \\ 0 & \dots & 0 & 1 & \gamma & \gamma^2 & \dots & 0 & \dots \\ 0 & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \ddots \end{bmatrix} \quad (6)$$

where γ is the discount factor. Following the linear MMSE estimator, we assume that the immediate rewards follow a Gaussian Process defined as $\mathbf{r} \sim \mathcal{N}(\mu_{\mathbf{r}}, \mathbf{C}_{\mathbf{rr}})$ where $\mu_{\mathbf{r}}$ is the a priori mean and $\mathbf{C}_{\mathbf{rr}}$ is the a priori covariance defined by an appropriate kernel [2]. Using the theorem of conditional distribution of multivariate Gaussian distributions [34], conditional expectation of immediate rewards given delayed rewards $\mathbb{E}[\mathbf{r}|\mathbf{R}]$ or the posterior mean of immediate rewards is:

$$\mathbb{E}[\mathbf{r}|\mathbf{R}] = \mu_{\mathbf{r}} + \mathbf{C}_{\mathbf{rr}}\mathbf{D}^T\mathbf{C}_{\mathbf{RR}}^{-1}(\mathbf{R} - \mathbf{D}\mu_{\mathbf{r}}) \quad (7)$$

and the posterior covariance $\mathbf{C}[\mathbf{r}|\mathbf{R}]$ of inferred immediate rewards given delayed rewards can be calculated as:

$$\mathbf{C}[\mathbf{r}|\mathbf{R}] = \mathbf{C}_{\mathbf{rr}} - \mathbf{C}_{\mathbf{rr}}\mathbf{D}^T\mathbf{C}_{\mathbf{RR}}^{-1}\mathbf{D}\mathbf{C}_{\mathbf{rr}}^T \quad (8)$$

where $\mathbf{C}_{\mathbf{RR}} = \mathbf{D}\mathbf{C}_{\mathbf{rr}}\mathbf{D}^T + \sigma_{\mathbf{R}}^2\mathbf{I}$ and \mathbf{I} is the identity matrix.

Algorithm 1 shows the process used to infer the immediate rewards. Estimation of the mean and covariance of the ran-

dom column vector \mathbf{r} in Eqs. 7 and 8 requires the inverse of the matrix $\mathbf{C}_{\mathbf{RR}}$. By introducing several intermediary variables, this algorithm provides an efficient solution to matrix inversion using the Cholesky decomposition similar to the Gaussian Processes algorithm implementation [34].

Algorithm 1 Immediate reward approximation algorithm.

Inputs: $\mathbf{R}, \mu_{\mathbf{r}}, \mathbf{C}_{\mathbf{rr}}, \mathbf{D}, \sigma_{\mathbf{R}}^2$
 $\mathcal{L} = \text{Cholesky}(\mathbf{D}\mathbf{C}_{\mathbf{rr}}\mathbf{D}^T + \sigma_{\mathbf{R}}^2\mathbf{I})$
 $\beta = \mathcal{L} \setminus (\mathbf{R} - \mathbf{D}\mu_{\mathbf{r}})$ forward-substitution algorithm
 $\alpha = \mathcal{L}^T \setminus \beta$ back-substitution algorithm
 $\bar{\mathbf{k}} = \mathbf{D}\mathbf{C}_{\mathbf{rr}}^T$
 $\mathbf{v} = \mathcal{L} \setminus \bar{\mathbf{k}}$
 $\mathbb{E}[\mathbf{r}|\mathbf{R}] = \mu_{\mathbf{r}} + \bar{\mathbf{k}}^T \alpha$
 $\mathbf{C}[\mathbf{r}|\mathbf{R}] = \mathbf{C}_{\mathbf{rr}} - \mathbf{v}\mathbf{v}^T$
return: $\mathbb{E}[\mathbf{r}|\mathbf{R}]$ and $\mathbf{C}[\mathbf{r}|\mathbf{R}]$

5. POLICY INDUCTION

In this section, we will describe our ITS, the training corpus, our policy induction procedure, and theoretical evaluation results.

5.1 Logic ITS

The logic tutor used in this study is named Deep Thought (DT), and it uses a graph-based environment to solve logic proofs. It is used in the undergraduate level Discrete Mathematics class at North Carolina State University. To complete a problem, students iteratively apply rules to logic statement nodes in order to derive the conclusion node. DT automatically checks the correctness of each step and provides immediate feedback on any rule that is applied incorrectly. The tutor consists of 6 levels, with 3 to 4 problems per level. Each problem can be represented as Problem Solving (PS) or as Worked Example (WE). Figure 2 (left) shows the user interface for PS, and Figure 2 (right) shows the interface for WE.

Figure 2: User Interface for DT. Left: PS. Right: WE.

5.2 Training Corpus

Our training corpus contains 786 complete student trajectories collected over five semesters. On average, each student spent two hours to complete the tutor. For each student, the tutor makes about 19 decisions. From our student-system interaction logs, we extracted a total of 142 state features:

- **Autonomy:** 10 features describing the amount of work done by the student.
- **Temporal:** 29 features, including average time per step, the total time spent on the current level, the time spent on PS, the time spent on WE, and so on.

- **Problem Solving:** 35 features such as the difficulty of the current problem, the number of easy and difficult problems solved on the current level, the number of PS and WE problems seen in the current level, or the number of nodes the student added in order to reach the final solution.
- **Performance:** 57 features such as the number of incorrect steps, and the ratio of correct to incorrect rule applications for different types of rules.
- **Hints:** 11 features such as the total number of hints requested or the number of hints the tutor provided without the student asking for them.

The features contain non-negative continuous values. As their range varies significantly (time can be a large number while problem difficulty is always between 1 and 9), we normalized each feature to the range $[0, 1]$. Input feature normalization has been shown to improve the stability of the learning process on neural networks, and often leads to faster convergence.

To induce our pedagogical policy, while previous research mainly used learning gains or time on task as reward function, our reward function here is based on the *improvement of learning efficiency*, which balances both learning gain improvement and time on task improvement. In this way, if two students have the same amount of learning gain, the one who takes shorter time would get higher reward. To calculate their learning efficiency, we used students' scores obtained on each level divided by the training time on the level. Students must solve the last problem on each level without help, and we use this as a level score. The range of the score for each level is $[-100, +100]$, and the learning gain for level L is calculated as $Score_L - Score_{L-1}$, thus having a range of $[-200, +200]$.

5.3 Training Process

For both DQN and Double DQN, we explored using Fully Connected (FC) NNs or using LSTM to estimate the action-value function Q . Our FC has four fully connected layers of 128 units each, uses Rectified Linear Unit (ReLU) as the activation function. Our LSTM architecture consists of two layers of 100 LSTM units each, with a fully connected layer at the end. Additionally, for either FC or LSTM, for a given time t , we explored three input settings: to use only the current state observation s_t ($k = 1$), to use the last two state observations: s_{t-1} and s_t ($k = 2$), and to use the last three: s_{t-2} , s_{t-1} and s_t ($k = 3$).

In the case of the fully connected (FC) model, the observations are concatenated and passed to the input layer as a flat array of values. For LSTM, the input state observations are passed to the network in a sequential manner. These past observations provide extra information about the performance of the student in the previous states. However, including previous states also add complexity to the network, which can slow down the learning process and can increase the risk of converging to a weaker final policy. As the number of parameters increases in the NNs, the chance that our NN would get stuck at a local optima increases, especially when our training data is limited. L2 regularization

Figure 3: Importance sampling results.

was used to get a model that generalizes better. We trained our models for 50,000 iterations, using a batch size of 200.

5.4 Induced Policy

First, we induced the DQN-Del policy using delayed rewards only. Our training data was split: 90% of the students for training data and 10% for testing data. We trained all 12 of our models (DQN and Double-DQN with either FC layers or LSTM layers, and with $k = \{1, 2, 3\}$) on the training data and evaluated their performance on testing data. We repeated this process twice with two different test sets and reported their average performance on a series of popular off-policy evaluation metrics. Among them, Expected Cumulative Reward (ECR) is the most widely used. However, Per-Decision Importance Sampling (PDIS) has shown to be more robust [31].

ECR is simply calculated by averaging over the highest Q-value for all the initial states in the validation set. The formula is described in Equation 9.

$$ECR = \frac{1}{N} \sum_{i=1}^N \max_a Q(s_i, a) \quad (9)$$

s_i is an initial state, and N denotes the number of trajectories in the validation set.

PDIS [31] is an alternative to regular Importance Sampling, to reduce variance in the estimations. The PDIS results of the 12 models are shown in Figure 3. The PDIS result of the random policy is used to set $y = 0$ (the red line) in Figure 3. Much to our surprise, while double DQN has shown to be much more robust in online DRL applications, its performance is generally worse than DQN here, especially when $k = 1$ and $k = 2$. Figure 3 shows that the best policy is induced using DQN with the LSTM architecture for $k = 3$, and thus is selected as DQN-Del. We also compare the selected policy with the remaining ones using ECR and other evaluation metrics and the results showed using DQN with the LSTM architecture for $k = 3$ is always among the best policies across different evaluation metrics.

To evaluate the impact of Inferred rewards on the DQN in-

Figure 4: ECR evolution of DQN-Del and DQN-Inf.

duced policies, we used the same approach to induce the DQN-Inf policy and the only major difference is that we used the inferred immediate rewards in the training dataset, calculated through Algorithm 1. During the training process, we calculated the ECRs of DQN with the LSTM architecture for $k = 3$ using the original delayed rewards (DQN-Del) vs. using the inferred immediate rewards (DQN-Inf). The evolution of the ECR values for each policy during the training process is shown in Figure 4, showing that using the inferred rewards we can theoretically converge faster and to a better policy.

6. EMPIRICAL EXPERIMENT SETUP

Two empirical experiments were conducted, one in the Spring 2018 semester and one in the Fall 2018 semester. They were both conducted in the undergraduate Discrete Mathematics class at North Carolina State University.

6.1 Experiment 1: Spring 2018

84 students from the Spring 2018 class were randomly assigned to the *Random* (control) group and the *DQN-Del* group. Because both *WE* and *PS* are considered to be *reasonable* educational interventions in the context of learning, we refer to our control random policy as a *random yet reasonable* policy or *Random* in the following. The assignment was done in a balanced random manner, using the pre-test score to ensure that the two groups had similar prior knowledge. $N = 45$ and $N = 39$ were assigned to *Random* and *DQN-Del* respectively. Among them, $N = 41$ *Random* students and $N = 33$ *DQN-Del* students completed the training. A χ^2 test showed no significant differences between the completion rates of the two different groups: $\chi^2(1, N = 84) = 0.053, p = 0.817$.

6.2 Experiment 2: Fall 2018

98 students from the Fall 2018 Discrete Mathematics class were distributed into two conditions. The two conditions are the *Random* (control) group and the *DQN-Inf* group. The group sizes were as follows: $N = 49$ for *Random*, and $N = 49$ for *DQN-Inf*. A total of 84 students completed the experiment and their distribution was as follows: $N = 43$ for *Random*, and $N = 41$ for *DQN-Inf*. A χ^2 test of inde-

pendence showed no significant differences between the completion rates of the two different groups: $\chi^2(1, N = 98) = 0.025, p = 0.872$.

6.3 Performance Measure

Our tutor is consisting of 6 strictly ordered levels of proof problems. All of the students received the same set of problems in level 1. Their initial proficiency is calculated based upon the number of mistakes made on the final problem of level 1 and the total training time on level 1. The proficiency reflects how well they understand the knowledge and can apply the logic rules in the proof process before the tutor follows different pedagogical policies. In each sequential level, DT will follow the corresponding policies to determine the next problem to be *WE* or *PS*. The last problem on each level is used as a mini-posttest to measure students' performance on that level.

When inducing both the *DQN-Del* and *DQN-Inf*, we calculated our reward function based upon the improvement of students' learning efficiency which is defined as level scores divided by the training time on that level. So to measure student performance, we first calculate the learning efficiency on each level as: the score obtained by the student in the last problem of that level, divided by the total time (in minutes). In this study, we use student learning efficiency in level 1 as their pretest efficiency score and their learning efficiency in level2-level6 as the post-test efficiency scores. Since our DQNs used learning efficiency improvement as their rewards, we expect that the DRL-induced policy would cause students to have higher post-test efficiencies.

7. RESULTS

7.1 Experiment 1 Results

No significant difference was found on the pre-test efficiency between the *Random* and *DQN-Del*: $t(72) = 1.086, p = 0.281$. We divided the students into high pre-test efficiency ($n = 37$) and low pre-test efficiency ($n = 37$) groups, based upon their learning efficiency on the pre-test. As expected, there was a significant difference between the high and low efficiency students on their pre-test efficiency: $t(72) = 9.570, p < 0.001$. The partition mentioned above resulted in four groups, based upon their incoming efficiency and condition: *DQN-Del-High* ($n = 16$), *DQN-Del-Low* ($n = 17$), *Random-High* ($n = 21$), and *Random-Low* ($n = 20$). A t-test showed no significant difference in the pre-test efficiencies either between the two low groups, *Random-Low* and *DQN-Del-Low*, or between the two high efficiency groups. These results show that there is no significant difference in the pre-test efficiency across conditions.

A two-way ANCOVA test on the post-test efficiency, using Condition $\{Random, DQN-Del\}$ and Incoming Competency $\{Low, High\}$ as factors and pre-test efficiency as a covariate, showed that there is no significant main effect of Condition $F(1, 69) = 2.633, p = 0.109$, and no significant main effect of Incoming Efficiency $F(1, 69) = 0.036, p = 0.849$. No interaction (ATI) effect was found either $F(1, 69) = 1.285, p = 0.261$. Thus, we conclude there was no difference between the two conditions in the Spring 2018 study.

Figure 5: Post-Test Learning Efficiency across different groups for the Fall 2018 study.

7.2 Experiment 2 Results

In fall 2018, again no significant difference was found on the pre-test efficiency between the Random and DQN-Inf groups: $t(82) = -0.333, p = 0.739$. The students were also divided into high pre-test efficiency ($n = 42$) and low pre-test efficiency ($n = 42$) groups. A t-test showed a significant difference between the high and low efficiency students on the pre-test efficiency: $t(82) = 6.38, p < 0.001$. The same four groups were formed, based upon their incoming efficiency and condition: DQN-Inf-High ($n = 20$), DQN-Inf-Low ($n = 21$), Random-High ($n = 22$), and Random-Low ($n = 21$). A t-test showed no significant difference on the pre-test efficiencies when comparing the Random-Low and DQN-Inf-Low groups: $t(40) = 0.027, p = 0.978$. No significant difference was found either, when performing a t-test on the two high efficiency groups: $t(40) = -0.698, p = 0.489$. This shows that there is no significant difference on the pre-test efficiency across conditions during the Fall 2018 study.

A two-way ANOVA test using Condition {*Random*, *DQN-Inf*} and Incoming Competency {*Low*, *High*} as two factors showed a significant interaction effect on students' post-test efficiency: $F(1, 80) = 5.038, p = 0.027$ (as shown in Figure 5). To be more strict, we ran a two-way ANCOVA test using Condition and Incoming Competency as two factors and pre-test efficiency as a covariate. This analysis also showed a significant interaction effect on students' post-test efficiency: $F(1, 79) = 4.687, p = 0.033$. Thus, by taking the pre-test efficiency into consideration, there is still a significant interaction effect. No significant main effect was found from either Condition or Incoming Competency. A one-way ANCOVA test on the post-test efficiency for the Low competency groups, using Condition {*Random-Low*, *DQN-Inf-Low*} as a factor and pre-test competency as a covariate showed no significant difference on the post-test efficiency $F(1, 39) = 0.429, p = 0.516$. However, a significant difference was found for the High groups $F(1, 39) = 5.513, p = 0.024$, with means -0.719 for Random-High and 2.916 for DQN-Inf-High (as shown in Figure 5).

7.3 Log Analysis

This section will show more details on the different types of tutorial decisions made across the different conditions and studies. The features that were analyzed include the total number of problems each student encountered (TotalCount), the number of problems solved (PSCount), the number of difficult problems solved (diffPSCount), the number of WEs seen (WECount), and the number of difficult WEs seen (diffWECount). Table 1 shows the summary of these five features for each condition and study. Columns 3 and 4 show the mean and standard deviation of each condition for these categories. Column 5 shows the statistical results of different t-tests comparing the two conditions.

No significant difference is found for the total number of problems seen by each group. However, we observed that for the features diffPSCount, WECount and diffWECount, a significant difference was found only during the Spring 2018 study. Looking at the mean values, we notice that the DQN-Del policy assigned fewer WE and more PS problems. However, this did not improve the performance of the students in the DQN-Del group during this study. During the Fall 2018 study, we only observe a significant difference in the number of PS problems assigned. No significant difference was found in the remaining categories.

When we analyze the logs for the High competency students, table 2 shows the values of those same features, but only for the High competency students in each study. During the Spring 2018 semester, we find a statistically significant difference for TotalCount, PSCount, and diffWECount, and we find a marginal difference for WECount. This shows that the DQN-Del policy gave more PS problems, fewer WE, and fewer difficult WE problems, but no significant difference was found in students' post-test performance. The Fall 2018 study results show no significant or marginal difference in any of the five categories. Despite this fact, the DQN-Inf policy implemented in the Fall 2018 study outperformed the Random policy for the High competency students. We can also observe how, in Table 2, the standard deviation for the DQN groups is often larger than the standard deviation for the Random groups. This makes sense because we expect all the students in the Random group to have a similar values in each category. However, it looks like the DQN policy is assigning more PS to certain students, and more WE to other students, resulting in a larger standard deviation.

In short, our log analysis results show that it is not about the total amount of PSs and WEs that students received that matters, but rather how or when they receive which.

8. CONCLUSIONS

We used offline Deep Reinforcement Learning algorithms in conjunction with inferred immediate rewards to induce a pedagogical policy to improve the students' learning efficiency for a logic tutor. Our results showed that our DRL-induced pedagogical policy can outperform the Random policy, which is a strong baseline here. More specifically, there was an ATI effect in the Fall 2018 study in that the high incoming competency students were benefited more from our DRL-induced policy, by achieving better post-test learning efficiency than other groups. Our results showed that our proposed Gaussian Processes based approach to infer "im-

mediate rewards” from the delayed rewards seems reasonable and works pretty well here. Thus, offline DRL can be successfully applied to real-life environments even with a limited training dataset with delayed rewards.

ABSTRACT

In this paper, we focus on optimizing the assignment of students to courses. The target courses are conducted by different teachers using the same syllabus, course design, and lecture materials. More than 1,300 students are mechanically assigned to one of ten courses taught by different teachers. Therefore, mismatches often occur between students' learning behavior patterns and teachers' approach to teaching. As a result, students may be less satisfied, have a lower level of understanding of the material, and achieve less. To solve these problems, we propose a strategy to optimize the assignment of students to courses based on learning activity analytics. The contributions of this study are 1) clarifying the relationship between learning behavior pattern and teaching based on learning activity analytics using large-scale educational data, 2) optimizing the assignment of students to courses based on learning behavior pattern analytics, and 3) demonstrating the effectiveness of assignment optimization via simulation experiments.

Keywords

Student assignment to courses, optimization, learning activity analytics

1. INTRODUCTION

Due to the widespread use of digital learning environments in education, collecting large-scale educational data has become easier in recent years. For example, online course educational systems such as Massive Open Online Courses (MOOCs) generate clickstream data from users who access the course websites. E-Learning systems such as Black-

board [5] and Moodle [9] record clickstream data when users submit reports, access materials, complete quizzes, etc. Educational data can also be extracted from e-Book systems (digital textbook systems), which provide precise logs of actions such as page movement, bookmarks, highlights, text memos, and so on. These large-scale educational data play a crucial role in the research domains of learning analytics and educational data mining.

Learning analytics is defined as the measurement, collection, analysis, and reporting of data about learners and their contexts for understanding and optimizing learning and the environments in which it occurs [1]. Various studies thus far have focused on learning analytics, including learning activity analysis [25], identifying at-risk students [17, 21], understanding learning paths [7], pattern mining [15], performance prediction [6, 14], and learning support [20].

In this paper, we focus on optimizing the assignment of students to courses. The optimization of assignment is often discussed for the purpose of timetabling problem [2, 18], teacher assignment to courses [8, 16], student assignment to courses [12, 19], and so on. The objective is to reduce the time consuming cost of educational office persons and faculty members, or to maximize the satisfaction of students and teachers. For these reasons, assignment problem is often applied to multi-different courses with consideration of the classroom capacities and preference of students and teachers. In contrast to these existing studies, the target courses of our study are conducted by different teachers using the same syllabus, course design, and lecture materials. More than 1,300 students are mechanically assigned to one of ten courses taught by different teachers. Therefore, mismatches often occur between students' learning behavior patterns and teachers' approach to teaching. As a result, students may be less satisfied, have a lower level of understanding of the material, and achieve less. To solve these problems, we propose a strategy to optimize the assignment of students to courses based on learning activity analytics.

The research questions and contributions of this study are

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 178 - 187

summarized as follows.

Research questions:

- RQ1.** Are learning activities common among courses or characterized by each individual course?
- RQ2.** Does better matching between the learning behavior pattern and teaching improve students' performance?

Contributions::

- C1.** Clarify the relationship between learning behavior pattern and teaching based on learning activity analytics using large-scale educational data.
- C2.** Optimize the assignment of students to courses based on learning behavior pattern analytics.
- C3.** Demonstrate the effectiveness of assignment optimization via simulation experiments.

In this paper, we review related research in the section 2 and then provide an overview of the proposed method including information about courses and the dataset in the section 3. The section 4 and section 5 discuss in detail the proposed method and strategy, and are followed by the discussion and conclusion in the section 6.

2. RELATED WORK

Optimization of assignment problem has been applied to several applications; such as timetabling problem [2, 18], classroom allocation problem [22], teacher assignment to courses [8, 16], student assignment to courses [24, 4, 12, 19], student grouping problem [11].

Elloumi et al. [2] defined the exam timetabling problem as the scheduling of exams to time slots, and the assignment of a set of exams to available classrooms. The objective was addressed to minimize the total capacity of the assigned classrooms. Phillips et al. [18] tackled the classroom assignment problem of university course timetabling. They solved an exact integer programming model for room assignment to get a Pareto optimal solution with respect to several solution quality measures on data from the university. Thongsanit [22] solved the classroom allocation problem. The number of students, the period of each course, the capacity of each classroom were used for optimization. Excel premium solver was applied to solve the problem.

Domenech et al. [8] solved the problem of teacher assignment to courses, taking teachers' preference into consideration. They developed a mixed integer linear programming model to balance teachers' teaching load and to maximize teachers' preference for courses. Ongy [16] also dealt with the teacher assignment problem to specific sections of particular courses. The assignment was solved to maximize the matching between teachers' competency to a specific subject. A mathematical model of the assignment process was formulated using mixed-integer programming.

Varone et al. [24] tackled the problem of course scheduling and assignment of students. They addressed students' preference for each course, a minimum number of students required to open a course, a maximum number of students for each course. The problem was defined as a generalization of

the student project allocation problem, and was solved by an integer programming problem. Ivo et al. [12] dealt with the problem of assigning students to elective courses according to their preference. They presented an integer programming model that maximizes the total student satisfaction in line with a number of different constraints. Shannon et al. [19] proposed an evolutionary algorithm for assigning students to courses. They addressed a situation where each student specified a set of courses with preference, and capacity of each course was given. The object was to maximize the overall student satisfaction by assigning each student to a course as high on his/her preference as possible.

As introduced above, optimization problems are often defined as a family of integer programming problem. One of common criteria is the capacity information such as classroom size, the number of students required by each course. In addition, taking preference of students or teachers into consideration will improve the satisfaction of them. In contrast to these studies, our study focuses on compulsory courses which all students have to join. The courses are conducted by several teachers in parallel, because of the limited capacity of each classroom. In compulsory courses, considering preference of students does not make much sense. Therefore, our method introduces a matching between learning behavior pattern and teaching which are objectively observed through the analytics of learning logs, instead of using subjective preference of students. To the best of our knowledge, our study is the first case to introduce the learning activity analytics results to optimizing student assignment to courses.

3. OVERVIEW OF METHODS

3.1 Lecture Course and Dataset

The dataset used in this study was collected from e-Learning and e-Book systems. The target courses were a series of lectures that constitutes the "Primary Course of Cyber Security," which commenced in Kyushu University in April 2018. Overall, 1,354 students were assigned to one of the 10 courses in advance. The lectures were conducted by six teachers in face-to-face style over seven weeks. Teachers followed the same syllabus and used the same lecture materials in the courses. Table 1 provides detailed information on the courses: teacher, course id and number of students. Note that in each course, four teachers were assigned to give two lectures each.

Table 1: Course Information

teacher	course id	students
Te01	60ab104927	114
Te01	6b1900c56c	120
Te02	9a683161f5	171
Te02	86066cba6d	143
Te03	792efa2c1b	139
Te03	34451e8c77	129
Te04	24a65f29b6	137
Te04	dbed6c966a	140
Te05	39a67f80f4	133
Te06	65bb6224af	128

All students have their own laptops and bring them to ac-

cess the e-Learning and e-Book systems during the lecture. We collected the learning activity logs over seven weeks. When an e-Book is operated, its timestamp, user id, material id, page number, and operation name are automatically recorded as an operation event. There are many types of operations; for example, OPEN indicates that a student has opened the e-Book file and NEXT indicates that the student has clicked the next button to move to the subsequent page. Students can bookmark a specific page, highlight selected characters, and make notes on a page. These operations correspond to the events ADD BOOKMARK, ADD MARKER, and ADD MEMO, respectively. A total of 4,087,730 e-Book operation logs were collected.

3.2 Analytics Flow

The analytics flow of this study comprises two stages. The first stage involves extracting the analytics of learning activities and quiz scores from each course. Statistical summaries of e-book operations, the browsing time for each page, and the distribution of the quiz scores for each lecture are analyzed to gather the characteristics of the courses. We then perform further detailed analytics of learning activities over courses to investigate the relationship between learning behavior patterns and quiz scores. We will show the possibility of optimizing the assignment of students to courses based on the results of these analytics.

At the second stage, we tackle the optimization issue, aiming to match learning behavior patterns and teaching to improve students' understanding of course contents. To this end, we use students' quiz scores instead of their level of understanding of course contents. We solve the optimization problem as a generalized assignment problem. We define a new cost function to realize the best assignment. We investigate the effectiveness of our assignment of students through simulation experiments.

4. LEARNING BEHAVIOR PATTERN ANALYTICS

There are several existing approaches to analyze learning behavior patterns in Massive Open Online Courses (MOOCs)[13, 10, 3]. On the other hand, our study focuses on learning logs collected during in-class, i.e., face-to-face lecture time, and out-class activities. Therefore, we newly design a methodology to analyze learning activities of students.

4.1 Course Activity Summary

The learning logs consist of four types of datasets: e-book operation logs, lecture material information, lecture time information, and quiz scores. First, we divide the e-book operation logs into in-class activity logs and out-class activity logs by referring to the lecture time information. With ten courses in the dataset, we acquire ten sets of in-class and out-class activity logs after the division procedure. Second, the in-class and out-class activity logs are aggregated page by page. The aggregation procedure is performed for each week (for seven weeks). This allows us to analyze the page-wise activity of each week. In addition, we calculate students' browsing time on each page by subtracting the timestamps between successive page transition events. Consequently, we acquire the total length of students' browsing time for each page.

Figure 1: In-class Learning activity, browsing time and quiz scores of each course in the 1st week.

Figure 1 shows the visualization result of in-class activity, browsing time, and quiz scores for the first week (The figure is arranged with 90-degree rotation due to the page space limitation). The figure on the left displays page-wise e-book operations including “BOOKMARK,” “HIGHLIGHT,” and “MEMO.” The horizontal axis represents the page number while the vertical axis shows the number of operations aggregated by the students. Each row corresponds to a single course. The central figure shows students’ page-wise browsing time during lectures. The vertical axis of this figure is the timed duration (seconds). The figure on the right displays the quiz score distribution. After the lecture every week, students answered quizzes (averagely 5 questions). The quiz scores are normalized between 0 and 5 (full marks). The horizontal axis shows the scores and the vertical axis represents the number of students. The distributions of operations, browsing time, and quiz score are characterized for each course. For instance, the e-book operations are recorded in the former pages much more than latter pages. Regarding students’ browsing time, a longer time was spent on the former pages rather than latter pages. The quiz scores are also characterized by courses. The courses in the seventh and eighth rows received lower scores compared with other courses.

Next, let us focus on sets of two specific courses conducted by the same teachers. Of six teachers, four (Te01, Te02, Te03, and Te04) have two courses, as summarized in Table 1. We can see that the visualized results are similar for courses conducted by Te01, Te02, and Te03 compared with those of other teachers. Especially in the case of Te01 and Te02, the frequency of the e-book operation logs and browsing time for e-books have common peaks. On the other hand, in the case of Te04, the distributions are not so similar between two courses compared with the cases of other teachers. Even so, the similarity of the two distributions are higher than the courses conducted by the other teachers. Figure 2 shows the summary of e-book operation usage and quiz scores of each course in the first week. In the case of bookmark, highlight and memo operations, the value represents the average usage of each operation per page. The quiz score is normalized between 0 and 1. The higher value implies that students used the operations frequently or received better quiz scores. This figure illustrates that the courses conducted by the same teachers have similar values. While we show the result of the first week only due to the page space limitation, a similar tendency was observed in the other weeks.

From the above results, we inferred the following points. First, teachers have their own teaching ways, which do not differ widely between courses. Second, students’ learning activities are strongly affected by the teaching ways. To investigate these hypotheses, we further analyzed course characteristics.

4.2 Learning Activity Features

If learning activities are affected by teachers, the activities in each course should form a cluster, and the clusters related to the same teacher should have more similar features than the other clusters. For the investigation, we define a feature vector $F_{u,l}$ that represents the learning activities of student u for a lecture material l .

Figure 2: Learning activities in the 1st week.

To simplify the mathematical formulation, the notation u is omitted from the following explanation. Let f_p be a page-wise feature vector in page p of the lecture material. The f_p has eight elements;

$$f_p = (b_p^i, h_p^i, m_p^i, t_p^i, b_p^o, h_p^o, m_p^o, t_p^o), \quad (1)$$

where b_p^* , h_p^* , and m_p^* are the number of operation logs of “BOOKMARK,” “HIGHLIGHT,” and “MEMO” recorded during $(*=i)$ /outside $(*=o)$ the lecture time. The t_p^i and t_p^o are the browsing time of page i during the lecture time and outside lecture time, respectively. A feature vector for a specific lecture material l containing l_N pages is defined by the concatenation of f_p as

$$F_l = (f_1, \dots, f_p, \dots, f_{l_N}). \quad (2)$$

For instance, when a lecture material l consists of 50 pages, the feature vector has 400 (8-dim \times 50 pages) dimensions. Note that, in fact, the feature vector is calculated for each student u defined as $F_{u,l}$.

We apply t-SNE (t-Distributed Stochastic Neighbor Embedding) [23] to investigate the similarity and dissimilarity of feature vectors within the course and among the courses. t-SNE is a technique for dimensionality reduction. It is often used for the visualization of high-dimensional datasets. It converts similarities between data points to joint probabilities and tries to minimize the Kullback-Leibler divergence between the joint probabilities of low-dimensional embedding and high-dimensional data. Figure 3 shows the visualization result in two-dimensional space. Courses are marked by color. We can see that the feature vectors distribute closely in the same course, while those of other courses make distinguishable clusters. From these results, we can say that learning activities are affected by teachers, as mentioned in the previous section.

4.3 Learning Activity vs. Quiz Score

Through analyzing e-book operation logs and learning activity features, we found that the learning activity itself is

Figure 3: Visualization of feature vectors by t-SNE.

characterized by courses, i.e., teachers who conducted the lectures. On the other hand, the relationship between learning activities and quiz scores was not addressed in previous analytics. Although learning activity (i.e., feature vector $F_{u,l}$) is similar in the same course, quiz scores are distributed widely, as shown in the right part of Figure 1. Therefore, it is important to perform a relation analysis between learning activities and quiz scores.

To extract the characteristics of learning activities, we apply the k-means clustering method to the set of feature vectors $F_{u,l}$ acquired from all students. Then, we investigate the quiz score of each cluster and each course. Note that the clustering is performed for all feature vectors without considering the course id information. In other words, the learning activity features are purely analyzed to generate clusters. Afterwards, we put the course id again to each feature vector to investigate the clustering result. Figure 4 shows the result of the first week when the number of clusters was set to be 5. The horizontal axis is the course id and the vertical axis is the cluster id (from 0 to 4, totally 5 clusters). The value of each cell indicates the average quiz score. For example, in the left column and fifth row, the score is 3. This means that the students in course id “60ab104927,” with learning activity in cluster id “4” received the score of 3 on an average. The cells with values of zero indicate that no student belongs to the cluster or the course. The detailed distribution of quiz scores in each cluster is shown in Figure 5. The horizontal axis is the cluster id, and the vertical axis is the number of students over courses. We can see that each cluster cannot be explained by quiz scores. Even in the same cluster, that is, even in the similar learning activity, some students received better scores while others received worse scores.

Figure 4 displays interesting and important characteristics of lectures. First, some clusters (e.g., cluster id 0) represent the characteristics of learning activities observed only in limited courses (e.g., course id “9a683161f5” and “86066c6ba6d”). In the case of cluster id 1, the corresponding learning activities are observed in all courses, but the average quiz scores are different. Students in course id “86066c6ba6d” received higher scores, while those in course id “24a65f29b6” received lower scores than in the other courses. On the other hand,

Figure 4: Average quiz scores of each cluster and each course when the number of clusters was 5 in the 1st week.

Figure 5: Quiz score description of each cluster in the 1st week.

each column also shows interesting characteristics of each course. For example, students belonging to cluster id 2 received high scores in course id “39a67f80f4,” while those in cluster id 3 received lower scores. In the case of course ids “60ab104927” and “792efa2c1b,” the scores of cluster id 3 are higher than those of cluster id 2. Therefore, our findings are summarized as follows. Even if learning activities are similar, quiz scores differ among courses. The characteristics of each course and its method of scoring quizzes are different for each cluster. We investigated these characteristics by changing the number of clusters from 3 to 29 (14 patterns) and found the same results. Due to length limitations, we only show additional results when the number of clusters was set to 15 in Figure 6. As the number of clusters increases, course-specific clusters appear, such as cluster id 1, 2, and 3.

5. OPTIMIZATION OF STUDENT ASSIGNMENT TO COURSES

Based on the results of the learning activity analysis and findings in the previous section, we optimize the process of assigning students to courses considering learning activities and course characteristics. In this section, we define the characteristic of courses c as the ability to give a student group g a quiz score $A_{c,g,l}$ on average for the lecture material l . Note that the lecture material l completely corresponds to each week, so that we can regard the l as the indicator of week. The c , g , and $A_{c,g,1}(l = 1)$ correspond

Figure 6: Average quiz scores of each cluster and each course when the number of clusters was 15 in the 1st week.

to the column, row, and element value in Figure 4, respectively. Our assumption is that students will get better quiz scores if they move to better-suited courses. For example, students in group $c = \text{"dbed6c966a"}$ and $g = 3$ received an average quiz score of 2.0 (i.e., $A_{c,g,1} = 2.0$). If they could move to another course, "792efa2c1b" , their quiz score would become 1.89 points higher (will receive 3.89 points on average). While this is an ideal situation, we suppose that a good match between course characteristics and learning behavior patterns will generate positive effects. Therefore, we propose an optimized strategy of assigning students to courses based on learning activity analytics.

5.1 Assignment Problem

The optimization of assignment can be considered the generalized assignment problem (GAP). The GAP is a problem in combinatorial optimization in which each agent in one set is matched to a single task in another set. Each task has a limited capacity for agents, and the goal is to minimize the sum of the costs or maximize the sum of profits. Formally, the problem can be stated as an integer programming problem.

In the case of our study, the agents and tasks can be replaced by the courses and students. The problem is:

$$\text{minimize } \sum_{c=1}^C \sum_{u=1}^U w_{c,u} x_{c,u} \quad (3)$$

$$\text{subject to } \sum_{u=1}^U x_{c,u} \geq S_c, \quad \text{for } c = 1, \dots, C \quad (4)$$

$$\sum_{c=1}^C x_{c,u} = 1, \quad \text{for } u = 1, \dots, U \quad (5)$$

where C is the number of courses, U is the number of students, and $w_{c,u}$ is the cost for the assignment of student u to course c . The detailed definition of $w_{c,u}$ will be explained later. The $x_{c,u}$ becomes 1 if student u is assigned to course c ; otherwise, it is zero. The S_c is the minimum of students required in course c .

We define the cost $w_{c,u}$ as follows:

$$w_{c,u} = (H - A_{c,m(u)}) + b \quad (6)$$

where H is the maximum quiz score, $m(u)$ is a map function that presents the group g (i.e., cluster id) to which the student u belongs, and b is the bias term to penalize changing courses. The first term $(H - A_{c,m(u)})$ becomes smaller when student u is assigned to a course c in which student u will likely receive a higher quiz score. In other words, student u belonging to group $m(u)$ is likely to move to a course that gives higher quiz scores for group $m(u)$. Note that $m(u)$ indicates the student group (cluster id) that has a similar learning activity within the group, so that we can estimate a quiz score $A_{c,m(u)}$ for every assignment situation because $A_{c,m(u)}$ corresponds to an element in Figure 4. The bias term b gives an additional cost to constrain the course movement (change of the assignment from one course to another). If we give a large value to b , the $w_{c,u}$ also becomes large, which most likely results in students remaining in the current course. Note that the above equations are calculated in each week so that the notation l , which identifies the lecture material, should be put on each term such as $w_{c,u,l}$, $x_{c,u,l}$, $A_{c,m(u),l}$. In the above equations, we omitted the notation l to simplify the mathematical formulation.

5.2 Assignment Results

We conducted experiments to investigate the proposed assignment strategy. We varied the number of clusters from 3 to 29 (14 patterns) and the bias b from 0.0 to 1.0. We performed k-means clustering to acquire the relation matrix of the quiz scores between student groups g and courses c as shown in Figure 4. Next, we solved the generalized assignment problem by changing the bias value to 0.0, 0.1, 0.3, 0.5, and 1.0. Assignment optimization was conducted for each week individually so that we acquired a total of 490 assignment results (14 clustering patterns \times 5 bias patterns \times 7 weeks). In the following paragraph, we report how the assignment result changed according to the number of clusters and the strength of the bias.

First, we investigated how many students were assigned (moved) to the other courses. Figure 7 shows the assignment results when the number of clusters was 5 and the bias was 0.5. Course ids are arranged in horizontal and vertical lines. The horizontal line indicates the course id to which students belonged before the assignment, that is, the original course assigned by the university. The vertical line shows the course id to which students were assigned after the optimization of the assignment problem. The value of each cell is the number of students. For example, 137 of 139 students who originally belonged to "86066cba6d" remained in the same course, but 2 students moved to the course "9a683161f5" . In the case of this result, the bias was set to be 0.5, which is a relatively strong bias to constrain course changes, resulting in students remaining in original courses (large value in diagonal element) rather than changing courses. Interestingly, a

Figure 7: Movement matrix when the number of clusters was 5 in the first week.

large movement occurred between course “dbed6c966a” and “39a67f80f4.” Figure 8 shows another result when the number of clusters was 15 and the bias was 0.0 (no bias). Compared with Figure 7, a larger number of students moved from their original courses to other courses.

Next, we investigated the total number of students who moved courses. Figure 9 shows the summarized result of course movement. The horizontal axis shows the number of clusters that we set when performing k-means clustering for learning activity logs. The vertical axis displays the percentage of students who were assigned to the other courses. The five lines represent the results with different values of bias. In general, as the number of clusters increased and as the value of bias decreased, many students were assigned to other courses. The larger number of clusters generated small clusters that precisely indicate the representative learning activities, which is why the flexibility of the matching between students and courses increased. In the case of no bias (bias $b = 0.0$), students moved among courses the most flexibly.

The flexibility directly related to the encouragement of quiz scores. Figure 10 shows the improved quiz scores after the optimization of student assignments. The vertical axis is the value of the improved quiz score. In fact, the improvement in the quiz score $\hat{q}_{u,l}$ of each student u for the lecture material l (i.e., l th week) was calculated by:

$$\hat{q}_{u,l} = q_{u,l}^{org} - A_{c,\hat{m}(u),l} \quad (7)$$

where $q_{u,l}^{org}$ is the original quiz score of student u in l th week and $\hat{m}(u)$ is the map function that gives the group id (cluster id) to which student u was assigned. The line graphs indicate the average of score $\hat{q}_{u,l}$ of all students over seven weeks. We can see the similar tendency of the line graphs compared with Figure 9. We further investigated the improvement of quiz scores in each week. We identified three typical cases:

Figure 8: Movement matrix when the number of clusters was 15 in the first week.

Figure 9: Course movement over 7 weeks.

2nd week: w2 the original score was higher on average than in other weeks.

4th week: w4 the original score was lower on average than in other weeks.

6th week: w6 the original score was at an average level over 7 weeks.

Figure 11 shows the line graphs of three cases; the solid line and dashed line correspond to the different settings of bias value at 0.0 and 0.5, respectively. The lower the original score (fourth week), the more the score was improved. From these results, we can expect to improve the quiz scores through the optimization of student assignments. The level of improvement is affected by the number of clusters and the value of bias. In addition, the number of course movements is strongly affected by the bias.

Finally, we note again that the experiments in this section demonstrate the success of the proposed optimization strategy based on the analytics of learning activities. Although

Figure 10: Score improvement after optimization of student assignment to courses.

Figure 11: Three typical examples of score improvement.

the improvement of quiz score $\hat{q}_{u,l}$ is a simulated result, we can expect students to get better scores if matching between students and courses is optimized. This expectation comes from the fact that matching optimization provided better scores, as shown in Figure 4 and 6 of the previous section.

5.3 Simulation in a Realistic Situation

In this section, we conduct simulated experiments considering a more realistic situation. The proposed optimization method requires students' learning activity logs to analyze learning behavior patterns and quiz scores. Therefore, we assume that the optimization of student assignment is performed after the lecture of the first week. Using the data from learning activities and quiz scores collected in the first week, we optimize the assignment of students to courses. The assignment then remains the same after the second lecture. We simulated the quiz scores of students who were assigned to another course after the first lecture from the second to seventh week.

This simulation is difficult because although the actual quiz scores in the original courses are known, quiz scores after the optimization of assignments are unknown. Therefore, we must estimate students' quiz scores after optimization. We will now review the purpose of clustering learning activi-

ties. As concluded in the previous section, students received different quiz scores even when their learning activities were similar. After the optimization of student assignment to courses, students who received worse scores in the original course should be moved to another course in which they will receive better quiz scores. Therefore, we will focus on a student who has a similar learning activity in the course to which the target student is assigned. More specifically, let a target student be y and consider a situation where student y is assigned to course c . For all students who originally belonged to course c , we search for a student z who has the most similar learning activity to student y . Mathematically,

$$z = \arg \min_u |F_{y,l} - F_{u,l}| \quad (8)$$

where $F_{u,l}$ is a feature vector of learning activity of student u for the lecture material l . The lecture material l corresponds to a specific lecture, so that we can regard l as the lecture conducted in each week. Finally, we regard the original quiz score $q_{z,l}^{org}$ of student z as the estimated score of the target student y . Let $\hat{q}_{y,l}^{new}$ be the estimated quiz score of student y after the assignment. The score improvement ratio $r_{y,l}$ can be calculated by:

$$r_{y,l} = \frac{\hat{q}_{y,l}^{new} - q_{y,l}^{org}}{H - q_{y,l}^{org}} \quad (9)$$

where H is the maximum quiz score (the same with eq. 6) and q_y^{org} is the quiz score of student y in the original course. Note that $q_{y,l}^{org}$ is the actual quiz score and $\hat{q}_{y,l}^{new}$ is the estimated quiz score. Figure 12 illustrates the overview of the simulation strategy. In the Figure, student y is assigned to course A after the 1st week. The quiz scores from the 2nd week to 7th week have to be estimated because the student y has the quiz scores in the original course B. Our strategy explore the most similar (matched) feature vector $F_{u,l}$ from the students in course A. In the case of this figure, the learning activities of student 1 and student 2 are the best matched in the 2nd week and 3rd week, respectively. As the results, the quiz score of $q_{1,2}^{org}$ and $q_{2,3}^{org}$ are used for the estimated quiz scores of student y in the 2nd week and 3rd week, respectively.

Figure 13 shows the simulation result. The horizontal axis shows the number of clusters, and the vertical axis represents the score improvement ratio. The improvement ratio is averaged over six weeks (from the 2nd to 7th week) and over students who moved from the original course to the other course. Totally, the improvement ratio of every setting (any number of clusters, or any value of biases) was higher than zero, which means that the student assignments created positive effects for students. The scale of the effect was the largest when we set the bias b to 1.0. In contrast to the result in Figure 10, the largest value of bias provided the best result. This is because the improvement ratio is summarized by students who were assigned to the other course only. In the case of a large value of bias b , the movement from one course to another is constrained, so that a small number of students actually changed courses, as shown in Figure 9. As a result, the optimization of student assignment provided higher effects (i.e., made students receive better quiz scores) for a limited number of students. As the number of students increases (the bias decreases), the effect becomes smaller due to averaging calculation of improvement ratios. There was

Figure 12: Overview of simulation experiment how to estimate the quiz scores in the newly assigned course

Figure 13: Average score improvement ratio over 6 weeks.

not a large difference of improvement ratios among the four settings where the bias value was 0.0, 0.1, 0.3, or 0.5 when the number of clusters was larger than five. In terms of the calculation cost and ease in explaining/interpreting learning activities, we prefer the smaller number of clusters, so that selecting the five clusters is one of the reasonable solutions.

Finally, Figure 14 shows the weekly improvement ratio when the number of clusters was fixed to be five. From the fourth (w4) to the seventh week (w7), a similar tendency was observed: The large value of bias b provided higher improvement. On the other hand, in the second (w2) and third weeks (w3), even the smaller value of bias b provided better results. We guess that the factor comes from the calculation of improvement ratio. When the original quiz scores are close to the maximum quiz score H , the denominator eq. 9 becomes smaller, resulting in a larger improvement ratio. In fact, the average of the original quiz scores in the second week was quite higher than in other weeks. In terms of maximization of the number of students who are supposed to get better quiz scores, the constraint bias should be relaxed as

Figure 14: Average score improvement ratio of each week when the number of clusters was 5.

least as possible. Therefore, a reasonable guideline to set the number of clusters and bias is to set a smaller number of clusters (such as 5 or 7) and set a smaller value of bias (such as 0.1, 0.3, or 0.5).

6. DISCUSSION AND CONCLUSION

We proposed a strategy to optimize the assignment of students to courses based on learning activity analytics. This optimization is first intended to minimize the mismatch between students' learning behavior patterns and teachers, and second to maximize the improvement of students' quiz scores by assigning them to courses that are more suited to their learning behavior patterns. The success of these interventions are supported by the learning analytics results. Analyzing e-book operation logs and quiz scores collected from 1,354 students in 10 courses based on the same syllabus and lecture materials, we identified the following findings. From the macro perspective, learning activities are affected by teachers. Although teachers are not directly observed by teaching logs, the patterns implicitly appear as course-specific features, as shown in Figure 3. From the micro perspective, students' learning activities can be grouped into several clusters, each cluster representing a feature of such learning activities. Regardless of courses, students have similar learning activity features if they belong to the same cluster. On the other hand, quiz scores differ among students who belong to the same cluster. From these facts, we formulated the hypothesis that good matching between learning behavior pattern and teaching approach would provide better effects for students.

Our proposed approach requires learning activity logs to be acquired before students can be assigned to courses. Thus, in our experiments, we used learning logs collected in the first week and then optimized the assignment of students for subsequent weeks. Another promising solution to this matter could employ learning logs collected in other lecture courses or in past courses. If such logs are available, learning activities can be analyzed in advance and students can be optimally assigned to courses before the first week's lecture begins. This paper showed the effectiveness of an optimization strategy through the results of simulation experiments in which quiz scores improved. Meanwhile, the proposed method has another important aspect as a useful tool to

simulate the effects of assignments in advance. In future work, we will investigate the effectiveness of the optimization strategy in live settings based on effect simulations.

ABSTRACT

The evaluation of text complexity is an important topic in education. While this objective has been addressed by approaches using lexical and syntactic analysis for decades, semantic complexity is less common, and the recent research works that tackle this question rely on machine learning algorithms that are hardly explainable and are not specifically designed to measure this variable. To address this issue, we explore in this paper the engineering of novel features to evaluate conceptual complexity. Through the construction of a knowledge graph that captures the concepts present in a text and their generalized forms, we measure different graph-based metrics to express such a complexity. Eventually, early-stage evaluations based on a well-known public corpus of students' productions show that the use of these metrics significantly improves performance compared to a state-of-the-art binary neural network classifier.

Keywords

semantic complexity, concept complexity, knowledge graph, features engineering, neural network, machine learning

1. INTRODUCTION

In Technology Enhanced Learning, the evaluation of the complexity of textual material underlies several activities. For instance, assessments in language classes are based, among other things, on the measurement of the learners' abilities to deal with different grammatical structures or to use the most precise vocabulary to express their thoughts. Another example can be found in learning resources indexation. Merlo [4] and Openstax¹ are two projects that aim at offering fine-grain information retrieval functionalities and automatic recommendation systems for educational objects based on their metadata, including their level of difficulty.

Complexity is usually related to readability, a concept defined as the "total sum of all those elements within a given

¹<https://openstax.org>

piece of printed material that affect the success a group of readers have with it" [5]. Thus, readability depends on both the object (the text) and the subject (the reader), whereas complexity is commonly characterized by a function whose output does not differ from one reader to another [11, 21].

Many research works in Natural Language Processing (NLP) sought out a way to measure the complexity of a text, and to predict the category (e.g. the level of difficulty) it should fall into. Most of them, nevertheless, focus on lexical and syntactic evaluation to achieve their objectives. Alongside the recent progress in machine learning, and more specifically in deep learning, another approach to text classification arose, based on semantic relationship of words within a text [17]. While offering outstanding performance, these predictive models are not easily explainable [28]. However, to provide this property is of importance to increase the confidence a user gives to these systems [1], and would allow to improve the usability of predictive models. For instance, a tutoring system designed for learning a foreign language would benefit from such a model, that is able not only to assess the complexity of a student's writing, but also to give suggestions on how to improve it.

Hence we propose in this paper a novel approach to measure semantic complexity with a model based on explainable features: we exploit the semantic web to build the conceptual representation of a text within an ontological graph, that we use to compute a set of metrics. In order to validate our model, we focus here on the following research questions:

- Is a model based on our sole metrics able to outperform a state-of-the-art model of semantic complexity?
- Does the extension of a state-of-the-art predictive model with our engineered features improves its performance?

In this paper, we answer these questions in the context of complexity assessment of students' productions in English as a foreign language. The first section is dedicated to related work in complexity assessment, in order to select a state-of-the-art model to compare to. We describe then the pipeline we designed to build a conceptual graph from a text and convert it into a vector, before going into the details of the 17 metrics that compose the vector. The fourth section is dedicated to the analysis of our model, in order to answer the research questions we defined previously.

Rémi Venant and Mathieu d'Aquin "Towards the prediction of semantic complexity based on concept graphs" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 188 - 197

2. RELATED WORK

Complexity, as a function of the text only [29], is involved in different tasks related to education. Classification of resource materials has become an important topic with the growth of open education and MOOCs [15], in order to provide suitable recommendations to a learner [3]. Learner evaluation would also benefit from such a function. Checking mistakes is not enough to assess the writing skill of a student; one also needs to measure the ability to express more complex thoughts, with the use of precise concepts [19]. A last instance of a task that requires complexity assessment is text simplification, a process that aims at providing a simpler version of a text by reducing its complexity, without removing its substantial content [25].

These objectives require computational models in order to classify them or to measure a value of complexity according to the needs. Different categories of metrics are involved to build such models, and most of the current research works rely on surface, syntactic and lexical features [8, 7, 24]. Surface level features provide basic statistical measures such as the number of characters or words. Lexical features target the structure of sentences, such as the average number of verb phrases per sentences or the number of dependent clauses [21]. Finally, syntactic features are based on the recognition of terms to compute metrics such as the average number of synonyms of words. Other morphological values (i.e., based on the structure of text) can be found. Siddharthan [29] proposed to measure discourse complexity to evaluate whether connections between text segments are vague or weak. In addition, Davoodi [8] used coherence features, that refer to the grammatical and lexical links which connect linguistic entities together, in order to include the influence of discourse structure on text complexity assessment. Similar features can be found in [24], who evaluated the lexical cohesion and the level of argumentation.

With these features, predictive models of complexity have already shown good performances. For instance, a SVM binary classifier using 117 parameters that belong to these categories of features achieved to classify Swedish texts according to their complexity with an accuracy of 98.9% [12]. Although widely used, surface and syntactic features work only on the structure of the text, while lexical features, using a base of knowledge for word recognition do not provide any semantic to these words. Thus, a few projects proposed different ways to add semantic information to their model. A good example of the different approaches to semantic complexity can be found in [6], who proposed a mixed model using a wide range of different operators, a few of them being related to semantics. Indeed, they used Latent Semantic Analysis (LSA), Latent Dirichlet Allocation (LDA), and a Word2Vec model to extract semantic features.

LSA [9] and LDA [2] are traditional machine learning techniques well-known for their efficiency to extract the topics of a text. Thus, a predictive model of complexity based on either LSA or LDA will detect the main topics of a text and use them to assess complexity. This method is then based on the assumption that some topic are more complex than others. There are, however, two disadvantages with this assumption. First, the model will fit the distribution of topics among the texts from the dataset used to train and test it,

which can be detrimental to its generalizability. Also, we assume here the texts that deal with the same topics are of the same complexity, an hypothesis that may be wrong.

In a different way, words embedding models such as Word2Vec [23] or GloVe [27] learn geometrical encodings of words from their co-occurrence information. Both model achieve to capture the semantics of “analogy”. For instance, computing the difference between vectors of words “king” and “queen”, then adding the vector of “princess” would give a result whose the closest known vector would be the one of the word “prince”. Both models perform well on different kinds of tasks, such as semantic relatedness (to predict the degree of semantic similarity between two words) or concept categorization. These models seem also to provide the best results in capturing semantic complexity [17].

Unfortunately, these techniques project words into an abstract linear space, mathematically meaningful, but hardly understandable. If we can have insights of the vectors’ relationships at the scale of words, as with the example given previously, their interpretations regarding complexity remains limited. At the scale of a text, where we usually compute the average vector of words, we do not know any method to interpret the resulting vector regarding the text complexity.

3. CONCEPTUAL GRAPH PIPELINE

Within the field of semantic analysis, the manipulation of concepts within a text is inherent to its complexity [18]. For instance, when concepts are numerous, abstracts, or not closely related to each other, readers may suffer from accessing their prior knowledge to understand the text [10]. We propose here a concept-based approach of feature engineering to assess semantic complexity.

An ontology (or knowledge graph) is a powerful model to represent concepts and their relationships. With the growth of research in the semantic web, cross-domain description of the world became available, and one of the most known nowadays is DBpedia². DBpedia is a crowd-sourced project to provide an open knowledge graph based on the information available in several Wikimedia³ projects. It provides thus the description in a structured and linked way of various concepts (e.g.: persons, places, organizations, movies, etc.). The English version describes more than 4 million entities so far, and localized versions are provided in 125 languages. Also, everything described in DBpedia is an entity structured through several ontologies (e.g., the DBpedia ontology, schema.org or YAGO). Our work is based on the exploitation of DBpedia and its ontologies to (i) capture conceptual entities from a text, (ii) build a concept graph that includes entities and their higher-order concepts, and (iii) transform the graph into a vector of features. We designed a pipeline to achieve these tasks, whose implementation in Python is open source and publicly available⁴. The pipeline, shown in Figure 1, is built over 5 main components: (i) a text preprocessor, (ii) an entity extractor, (iii) a concept enhancer, (iv) a graph builder and (v) a graph vectorizer.

²<https://wiki.dbpedia.org/>

³<https://www.wikimedia.org/>

⁴<https://github.com/afel-project/pySemanticComplexity>

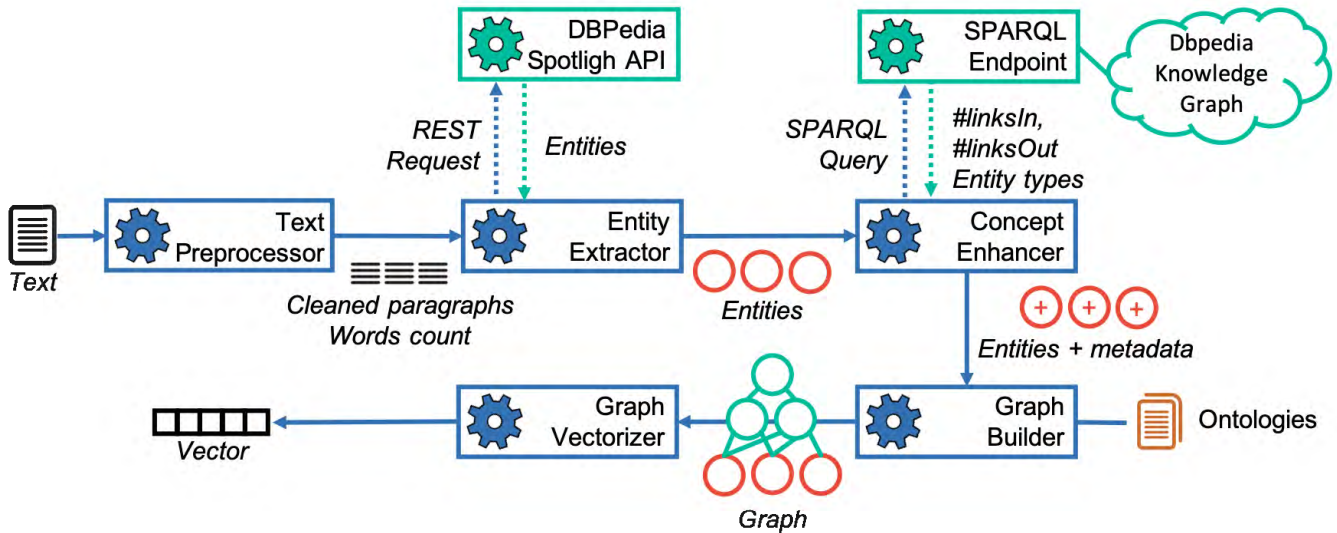

Figure 1: Text to Concept Vector Pipeline.

These software components can be launched separately, either in a stream or batch mode, to support distributing computing. Before we present them in the following subsections, we need to clarify the vocabulary we use to deal with concepts and concept graphs. A concept extracted from a raw text is named **entity**, to follow the vocabulary of DBpedia. An entity is related to some **types**, which are its direct higher-order concepts. Types are classes defined in the ontologies. A **higher-order concept** is a more abstract concept (i.e., a generalization of the concept). Within the ontologies, multiple inheritance relations exist between classes, and allow to structure the concepts they express in term of orders of abstraction. For instance, the “1965 ford mustang” is an entity with a type “collection car”, whose one of the higher-order concept is “car”, generalized itself into “vehicle”, then finally “object”.

3.1 Text preprocessor

Given a text document in a unicode format, this component (i) cleans it, with the deletion of forbidden characters, such as null or backspace, then (ii) splits the text into paragraphs (a prerequisite for the entity extractor that cannot process long text). The text preprocessor also computes the number of words (used for some of the metrics at the end of the pipeline) and the offset for each paragraph (used to locate entities within the whole text).

3.2 Entity Extractor

The entity extractor aims at extracting DBpedia entities from a given list of paragraphs. In order to extract such entities from a text, this component interacts with DBpedia through the REST interface exposed by DBpedia Spotlight⁵, a tool that performs named entity recognition [22]. Given a text, and quality parameters (i.e., prominence, topical pertinence contextual ambiguity and disambiguation confidence), the service returns a list of DBpedia entity URIs with their position in the text and some quality metrics. Thus, from

⁵<https://www.dbpedia-spotlight.org/>

a list of paragraphs, this pipeline stage retrieves a set of DBpedia URI with their positions in the document.

3.3 Concept Enhancer

This stage takes a list of entities and, for each of them, retrieve (i) its related types (second-order concepts), (ii) the number of entities that point to it ($\#linksIn$) and (iii) the number of entities it points to ($\#linksOut$). As we explained before, the entities in DBpedia are represented in a knowledge graph, where entities are linked each other, and described through different ontologies. $\#inLinks$ and $\#outLinks$ are computed based on the relationship between entities in DBpedia.

In order to retrieve all these types for the list of entities, the component interrogates a SPARQL Endpoint. SPARQL (recursive acronym which means SPARQL Protocol and RDF Query Language) is a SQL-like query language to retrieve or manipulate data in the RDF (Resource Description Framework) format, used in DBpedia. The concept enhancer fetches in a first request all the types that are related to each entity of the list. Two others requests are achieved to compute $\#linksIn$ and $\#linksOut$ for each entity. Finally this stage returns the list of entities enhanced with their types and the two basic metrics.

3.4 Graph Builder

The role of the graph builder is twofold: (i) to retrieve the higher-order concepts related to types given along with the entities, and (ii) to build an acyclic graph of all concepts.

The higher order concepts are the super-classes of the types that have been previously retrieved. Indeed, the ontologies used in DBpedia provide a hierarchical structure of classes, where each class may have one or several parent classes. In other words, a concept C may have one or several parents (higher-order concepts), that generalize C and its sibling.

In order to retrieve theses higher-order concepts, the graph builder does not need to interact with any DBpedia end-

Figure 2: Example of a Concept Graph.

point. This component loads directly the structure of ontologies, which are RDF files that can be locally processed. In our pipeline, we exploit the three most used ontologies in DBpedia: the DBpedia ontology, schema.org and YAGO. For each given type that belongs to one of the three ontologies, the graph builder recursively retrieves its parent concepts. As a result, the component constructs a set of pairs $\langle \text{child concept}, \text{parent concept} \rangle$ and, with the given list of entities, builds a concept graph of the text.

This graph is an acyclic graph composed of two kinds of vertices: entities (that appear in the text) and higher-order concepts (classes from the ontologies). An entity vertex has the following attributes: (i) the DBpedia URI, (ii) the list of positions in the text (word index) (iii) the $\#linksIn$ value and (iv) the $\#linksOut$ value.

While an entity may appear several times in the text, it is represented as a single vertex in the graph. However, its different positions are recorded in its attributes. The other vertices (higher-order concepts) contain only their URI. In order to ensure the graph is connected (a mathematical property required to compute some of the features explained in the following section), an abstract highest-order vertex is inserted and linked to any vertex that does not have any higher-order concept.

We illustrate in Figure 2, an example of a graph computed from the text “This computer has a powerful graphic card that is suitable for video games and machine learning.”. Entity nodes are colored in red, while higher-order concepts are in green (the abstract highest-order concept is in blue). In this example, the Spotlight API extracted 4 entities from the DBpedia ontology: “video game”, “computer”, “video card” and “machine learning”. The green nodes on the graph are then classes of this ontology that generalize the concepts they are connected to. Thus, a video game is a software, which is a work, whose generalized concept is a thing.

3.5 Graph Vectorizer

Giving the graph, and the number of words computed in the first stage of the pipeline, this last component applies several calculus in parallel to produce 17 metrics. The values are embedded in an vector, which is the final output of the pipeline. This vector can be used afterwards as an input for a predictive model on conceptual complexity.

4. CONCEPT COMPLEXITY METRICS

In this section, we explain the metrics that highlight specific information about the conceptual complexity, based on the structure of the generated graph. The 17 metrics computed by the pipeline are the following: (i) $\#concepts$, (ii) $\#distinctConcepts$, (iii) $conceptsByWords$, (iv) $distinctConceptsByWords$, (v) \muTypes , (vi) \sigmaTypes , (vii) $\mu linksIn$, (viii) $\sigma linksIn$, (ix) $\mu linksOut$, (x) $\sigma linksOut$, (xi) $\#nodes$, (xii) $Radius$, (xiii) $Diameter$, (xiv) $Density$, (xv) $Assortativity$, (xvi) $\mu TextDensity$ and (xvii) $\sigma TextDensity$. We details them in the following subsections.

4.1 Basic Concept Metrics

The first four metrics are measures based on the entities extracted from the text. $\#concepts$ is the total count of concepts the entity extractors retrieved, while $\#distinctConcepts$ is the number of the different concepts extracted. These metrics are based on the assumption that the more concepts a text deals with, the more complex it is.

Since these features might be correlated to the size of the text (which, as explained later, was not the case in our experiments, but still might be), we also propose **concepts-ByWords** and **distinctConceptsByWords**, the ratio between $\#concepts$ and $\#distinctConcepts$ respectively, and the number of words.

4.2 Concept Connection Metrics

The six following indicators relate the direct properties of the concepts that appear in the text. \muTypes and \sigmaTypes are respectively the mean and standard deviation of the number of types per entity. As explained before, each concept extracted from the text is linked to its types (i.e. its direct higher-order concepts). We suppose here that the more an entity has types, the more concepts of higher-order are required to explain it, and thus the more complex this entity is. We use the two basic statistic descriptors to capture that notion at the scale of a document.

For each entity in our graph e , we also have $\#linksIn$, the number of links that go from entities of the global DBpedia knowledge graph to e , and $\#linksOut$, the number of links that go from e to others entities of that same graph. We compute then two statistic descriptors for each indicator at the document level. $\mu linkIn$, $\sigma linkIn$ are respectively the mean and standard deviation of the number of entities in DBpedia that point to the entities of the document, while $\mu linkOut$ and $\sigma linkOut$ are about the entities in DBpedia that are pointed by the entities of the document. We suppose here that the more relations an entity has with others, the more popular it is, and the less complex it might be.

4.3 Concept Abstraction Metrics

The next five metrics take into account the whole concept graph: the entities, their types and the higher-order concepts retrieved recursively from the ontologies.

$\#nodes$ is the total number of nodes in the graph. The higher it is, the more concepts have been used or the more specific they are (i.e., the more higher-order concepts there are to specify them).

Figure 3: Examples of radius and diameters.

For the next metrics a formalism is required. Let $G = (V, E)$ the definition of a graph G with V the set of vertices (the concepts) and E the set of edges. Let $\forall(u, v) \in V^2$, $d(u, v)$ the distance between the nodes u and v : the number of edges in the shortest path. Since our graph is connected (thanks to the abstract higher-order concept node) and undirected, we have the following properties:

$$\forall(u, v) \in V^2, d(u, v) \geq 1, d(u, v) = d(v, u) \quad (1)$$

Interpreted in our context, the distance between 2 concepts shows how close they are from each other. Since concepts are linked by their higher-order concepts, the distance is the length of the path from one concept c_1 to another concept c_2 , going through their closest common higher-order concept. Thus, the distance measures how much we have to generalize to find the common inherent concept to relate c_1 and c_2 .

ϵ is the eccentricity of a vertex v . It is defined as the greatest distance between v and any other vertex of the graph.

$$\forall v \in V, \epsilon(v) = \max_{u \in V} d(v, u) \quad (2)$$

In our context, the eccentricity for a concept c_1 gives a measure of how far this concept is from the others.

4.3.1 Radius and Diameter

Based on this eccentricity, the **radius** r_G is the minimum eccentricity of any vertex in the graph.

$$r_G = \min_{v \in V} \epsilon(v) = \min_{v \in V} [\max_{u \in V} d(v, u)] \quad (3)$$

At the opposite, the **diameter** of a graph d_G is the maximum eccentricity of any vertex in the graph.

$$d_G = \max_{v \in V} \epsilon(v) = \max_{v \in V} [\max_{u \in V} d(v, u)] \quad (4)$$

On the one hand, the diameter highlights the “spreadness” of concepts: the more unrelated and specific concepts we have, the higher the diameter will be. On the other hand, the radius points to the “compactness” of concepts out: the more the concepts are closely related to each other, the lower the radius will be. Note that the radius is not strictly the opposite of the diameter; both metrics measure information that are not theoretically linearly dependent. To have an insight of their meaning, Figure 3 shows different simple graph structures with their radius and diameter.

4.3.2 Density

The **density** of a graph stresses how much nodes are connected to each other. A graph is dense if the number of edges is close to the maximal possible number of edges. The opposite is a sparse graph, that has few edges. The density is computed by the following equation:

$$0 \leq \mathcal{D}_G = \frac{2|E|}{|V|(|V| - 1)} \leq 1 \quad (5)$$

Here, a concept graph with a high density implies that concepts and higher-order concepts are closely related to each other. The text may deal with many different concepts, but many of them share parents concepts and so on. Density may then be a factor of discrimination regarding two texts that have similar numbers of concepts, but with one using concepts from a unique domain while the other one deals with varied concepts.

4.3.3 Assortativity

Following Newman [26], the **assortativity** measures in a graph the similarity of connections with respect to the vertex degree. The degree is the number of connections (the number of edges) a vertex has to other vertices. Mathematically, the assortativity is the Pearson correlation coefficient of degree between all pairs of vertices. It is computed by the following equation:

$$\mathcal{A}_G = \frac{2 \sum_i j_i k_i - \frac{1}{2} |E|^{-1} (\sum_i j_i + k_i)^2}{\sum_i (j_i^2 + k_i^2) - \frac{1}{2} |E|^{-1} (\sum_i j_i + k_i)^2} \quad (6)$$

where j_i, k_i are the degrees of the vertices at the ends of the i^{th} edge, in a graph with $|E|$ edges.

Because \mathcal{A}_G is a correlation coefficient, it lies between -1 and 1 . When it is close to 1 , the graph shows a perfect assortative mixing: the vertices in the network that have many connections tend to be connected to the other vertices with many connections. When \mathcal{A}_G is close to -1 , the graph is disassortative: the nodes that have many connections tend to be linked to the nodes with few connections. When \mathcal{A}_G is close to 0 , the graph is non assortative: there is no particular correlation between node connections and their degree.

Because in our concept graphs, concepts (vertices) are connected only by their relationship of abstraction (a parent concept being a more general concepts), a positive assortativity would signify that the more parents a concept requires to be defined, the more grand-parents these parents have. Under the hypothesis that the more higher-order concepts we need to define a concept c , the more complex c is, the assortativity may be a candidate metric to evaluate complexity: a graph with a high assortativity may highlight a text that deals with very complex and precise concepts.

Compared to the μ Types indicator, which is only computed on the basis of entity types, this metric takes into account the whole graph. For instance, if the text uses very narrowed concepts, that have only few types, which are however defined by many higher-order concepts, μ Types would be low, but assortativity may be close to 1 .

4.4 Concept Organization Metrics

While the previous metrics are about the graph only, they do not take into account the positions of the different entities

within the text. Although they provide conceptual information about the overall document, they lack giving insight about the evolution of complexity at a local level. For instance, a paragraph that deals with closely related concepts may be simpler than a paragraph that manipulates different unrelated concepts. Thus two texts that handle similar concepts, but with a different structure, may have a different complexity. In order to capture such information, we have built a metric based both on the concept graph and on the positions of the entities within the text.

Let $N \subset V$ the subset of vertices that contains the entities. As we explained in the previous section, the entities include the list of the positions of their occurrences. Let $occ(e)_i \forall e \in N$ the position of the i^{th} occurrence of the entity e in the text. We define the function sp of two entities that returns the shortest path in the text between the two concepts.

$$\forall(n, m) \in N^2, sp(n, m) = \min_{i,j} |occ(n)_i - occ(m)_j| \quad (7)$$

On the basis of sp , we define the textual density td between two entities as the product of their graph distance d and the opposite of their textual distance td , normalized by the product of the graph diameter D_G and the text length L_T .

$$\forall(n, m) \in N^2, td(n, m) = \frac{d(n, m)}{D_G} \cdot \frac{1 - sp(n, m)}{L_T - 1} \quad (8)$$

Since $0 \leq d(n, m) \leq D_G$ and $0 \leq sp(n, m) \leq L_T - 1$, we have $0 \leq td(n, m) \leq 1$. When td is near 0, the concepts are either semantically very close, or unrelated and far to each other in the text. When td is close to 1, the concepts are semantically far to each other but appear closely in the text. At the document scale, we compute then the two last metrics $\mu\text{TextDensity}$ and $\sigma\text{TextDensity}$ that are respectively the mean and standard deviation of the textual density of all pairs of entities.

5. CONCEPTUAL COMPLEXITY ASSESSMENT EVALUATION

In this section, we seek to evaluate the performance of a classifier that predicts complexity, based on the concept metrics defined above. In order to analyze the impact of our features on such predictive models, we carried out several rounds of evaluation. We started building a binary classifier based on the state-of-the-art features to obtain a model of reference. To answer our first research question, “Could a model based on our sole metrics outperform a state-of-the-art predictive model of semantic complexity?”, we trained another classifier that uses our conceptual complexity features only and compared it with the first one.

Afterwards, we considered the second question: “Does the extension of a state-of-the-art predictive model with our engineered features improves its performance?”. To compare two models, one being an extension of the other, we trained our two models on the same splits of data (within a cross-validation procedure) and compared the two lists of mea-

sures of performance with a statistical test to assess whether the performances of the extended model was significantly higher than the performances of the first one.

Finally, since results were positive with respect to question 2, we trained a last classifier based on syntactic, lexical and semantics features, to evaluate how well it could perform for the specific task of predicting the overall complexity of learner’s productions.

5.1 Dataset

All models here were trained on an extract of the EF-Cambridge Open Language Database [16, 13]. This database is a text corpus of documents written by adult learners of English as a foreign language. In this study, we use a subset of this database, that includes 41 626 essays.

Human examiners evaluated these essays in order to assess the learners’ level of knowledge defined in the global scale provided in the Common European Framework of Reference for Languages⁶. This scale define 6 levels of knowledge (i.e.: A1, A2, B1, B2, C1 and C2), that describe skills in reading, listening, speaking and writing. Regarding this last domain of competency, A1 and A2 levels target beginners: they can interact in a simple way, using familiar everyday expressions and very basic phrases. Independent users belong to the B level group. Compared to level groups A and C, this group presents a clear difference between its two levels. While B1 users can produce simple connected texts on topics that are familiar, B2 users are able to write clear and detailed text on a wide range of topics and give their point of view on a topical issue. Finally, C1 and C2 levels target proficient users, that can handle complex subjects and produce clear, well-structured and detailed texts.

Thus, in this dataset, examiners labeled learners’ essays with one of these levels. Although there is no formal description about the evaluation process, the definitions provided in the global scale of the framework relate to the different kind of complexity we exposed earlier (i.e.: syntactic, lexical and semantic). For this study, we define two categories of writings based on these labels. The documents evaluated with a level between A1 to B1 are considered in the G1 group, while the documents evaluated with a level between B2 to C2 belong to the G2 group.

Outliers were removed from the dataset. They were defined here as the documents where the number of words were below the first centile or above the last one, or where the number of concepts were again, below the first or above the last centile. Since the distribution of documents between G1 and G2 was skewed, we reduce the dataset to obtain an equal proportion of samples in each group. The baseline score of a binary classifier is then 0.5 for accuracy, precision or recall.

Also, we detected a potential bias in the dataset, as the samples in G2 tend to be longer (in numbers of words) than the ones in G1. To prevent our models from reproducing that bias, we filtered all conceptual features we explained previously that would present a significant correla-

⁶<https://www.coe.int/en/web/common-european-framework-reference-languages/level-descriptions>

tion ($r \geq 0.75$, $p\text{-value} < 0.003$) with the length of the text (p-value was computed using the Bonferroni correction since we computed different statistical tests, which raise then the risk to produce a statistical type I error). It appears that none of the 17 features were significantly correlated to the length of the text as much as this threshold. Finally, we examine the potential relationship between pairs of features, to assess their independence and to avoid training our models with correlated features. We looked for strong significant correlations: $r \geq 0.9$ with $p\text{-value} \leq 0.0004$ (again, p-value was computed using the Bonferroni correction). It appears that only #concepts and #distinctConcepts are strongly correlated ($r = 0.936$). We then decided to remove the latest feature from our models for this dataset.

5.2 Baseline Model Evaluation

In order to produce a baseline binary classifier of semantic complexity, we applied the following methodology: (1) compute a 300 dimensional average vector for each sample based on pre-trained Glove vectors ; (2) train different types of classifiers using 5-folds cross validation, with default hyperparameters for each of them; (3) select the model that provides the best f1 score; (4) split the whole dataset into one subset for hyper parameters tuning (90%), and one subset for final testing (10%); (5) tune the hyper parameters of this model using a grid search 10-folds cross validation and (7) test the final model on the last subset.

Glove is an unsupervised machine learning algorithm used to compute vector representation for words, proposed by Stanford University [27]. Based on the word-to-word co-occurrence statistics obtained from a corpus, GloVe computes a representation of words into a vector space. In our case, we did not train such a model from scratch on our dataset, but used pre-trained words vectors available online⁷. These vectors were computed from the 2014 corpus of Wikipedia and the 5th edition of English Gigaword⁸, in a 300 dimensions space. For each sample from our dataset, we computed the mean of the tokenized words vectors, using 0 padded vectors for unknown words. The tokenization process was achieved using the NIST Tokenizer⁹.

The main scoring metric we used to evaluate our models is the f1-score. This metric takes in account both precision and recall through the following formula: $2 \cdot P \cdot R / (P + R)$, given the precision P (the ratio between the number of true positives and the sum of the number of true positives and false positives) and the recall R (the ratio between the number of true positives and the the sum of the number of true positives and false negatives). This metric is a value between 0 (the worst) and 1 (the best).

In step 2, we tested 10 different models. Each model was a pipeline made of two stages: a pre-processing stage to standardize features by removing the mean and scaling to unit variance, and the classifier stage. The results for the classifiers selection are shown in Table 1. The best classifier was the multilayer perceptron (MLP); it achieved the best f1 score, but also the best average accuracy. MLP is a type of

Table 1: Glove-based Models Performances.

Classifier	μ F1	μ Accuracy
MLP (1 hidden layer of size 100)	0.936	0.935
SVC with rbf kernel	0.936	0.934
K-nearest neighbors	0.917	0.910
SVC with polynomial kernel (d=2)	0.916	0.911
Quadratic discriminant	0.907	0.905
SVC with linear kernel	0.899	0.897
Random Forest (100 estimators)	0.896	0.892
AdaBoost	0.865	0.862
Gaussian Naive Bayes	0.826	0.811
Decision Tree	0.811	0.810

feedforward neural networks composed of at least one hidden layer of nodes, where each node in the hidden and output layers uses a nonlinear activation function [14].

In the last step, we tuned the following hyperparameters of the MLP model, given with their set of evaluated values: **(i)** the activation function (logistic, hyperbolic tangent or Rectified Linear Unit), **(ii)** the regularization term α (0.0001, 0.001, 0.01, 0.1 or 1.0), **(iii)** the size of each hidden layer (100 or 200), **(iv)** the number of hidden layers (1 to 5), **(v)** the learning rate (constant or adaptive) and **(vi)** the solver used for the weight optimization (adam or lbfgs).

We tested the different combinations of hyperparameters with a grid search 10-folds cross validation on a stratified subset of 90% of our dataset, using the mean test f1 value as the scoring method. The best configuration appears to be a MLP with one hidden layer of 200 nodes using a ReLU (Rectified Linear Unit) activation function, an α value of 0.01 with an adaptive learning rate and an adam solver.

Table 2: Test Scores of the Baseline and Concept Based Models.

Score	Baseline M. Values	Concept M. Values
F1	0.937	0.888
Accuracy	0.939	0.889
Precision	0.982	0.894
Recall	0.896	0.882

Eventually, we tested that classifier on the remaining 10% of our dataset. The different metrics are exposed in the column “Baseline M. Values” of Table 2. The Precision-Recall curve is illustrated in Figure 4a. Overall, this baseline classifier shows better precision than recall. As we can see on Figure 4a, recall tends to drop quickly as precision goes over 0.9. Recall is defined as the ability for the classifier to avoid false negatives. In our context, recall is thus the ability for the model to avoid predicting a text as being simple while it is in reality complex. In other terms, this models is better at predicting a text as being complex, than predicting a text as being simple.

5.3 Concept Based Model Evaluation

On the basis of the pipeline architecture elicited previously, we trained and tested an equivalent model that works with our 16 elicited engineered features only. The model is then composed of a standardization stage and an MLP classifier

⁷<http://nlp.stanford.edu/data/glove.6B.zip>

⁸<https://catalog.ldc.upenn.edu/LDC2011T07>

⁹http://www.nltk.org/_modules/nltk/tokenize/nist.html

(a) Baseline Model.

(b) Concept Features-Only Model.

Figure 4: Precision-Recall Curves of Baseline and Concept Features-Only Models.

with the previous selected hyperparameters. This model was trained in a stratified 10-folds cross validation on 90% of the dataset and tested with the remaining 10%. The results are given in the third column of Table 2. The Precision-Recall curve is illustrated in Figure 4b.

Using only the conceptual graph-based features, we can see that this model is worst than the baseline one to predict complexity. The drop of score value is around 5% for F1 and accuracy, and 8% for the precision. In conclusion, to answer to our first research question, using the features we proposed only, we cannot outperform a model based on the state-of-the-art semantic features to predict complexity.

5.4 Baseline and Mixed Model Comparison

Whereas the model based on conceptual features failed to outperform the baseline classifier, these metrics might still add information that are not present from the state-of-the-art semantic features. Thus, we need to study whether a classifier would do better with both sets of features.

In order to assess such a result, and because the two classifiers will not be independent, we need to evaluate whether the performance scores of these classifiers have a significant difference of mean. We trained two classifiers, CL_{base} and CL_{mixed} with the same architecture than the one selected previously: a standardization pre-processing stage chained to a MLP classifier with the former chosen hyperparameters. CL_{base} is the baseline classifier that uses the Glove features only, while CL_{mixed} uses both Glove and our conceptual graph-based features. In order to compare the difference of performances, we evaluated our classifiers with the same splits of a stratified 10-fold cross validation scheme.

The results for the 4 metrics (F1, accuracy, precision and recall) for CL_{base} and CL_{mixed} on each fold are given in Table 3. The metrics observed for CL_{mixed} seem to be better than CL_{base} . However, to assess whether this difference is significant, we proceed a paired sample Student's T-test, since the measurements of each classifier were applied on the same splits of data.

The Table 4 presents the statistical results of the paired T-test. The null hypothesis is that the pairwise difference between the two tests for each metrics is equal. With the degrees of freedom $df = 9$ (as we achieved 10 measures),

and a p-value of 0.05, the t-table value is 1.812. For each metrics, we can see on Table 4 than the computed t-value has a absolute value above 1.812. We can then rejected the null hypothesis that there is no difference between means for each metrics. In conclusion, adding conceptual graph-based features to Glove features improve significantly the performance scores of our complexity classifier. We therefore answer positively to our second research question.

5.5 Extended Complexity Classifier

Thus, conceptual graph-based complexity features can increase the performances of complexity classifiers, while improving the explainability of the model. In our context of evaluating learners' production in English to assess their complexity, we eventually would like to test how a complete classifier, using not only semantic features but also syntactic and lexical ones, would perform.

In that last part, we trained and tested a supervised classifier that predicts complexity based on the previous semantic features, and syntactic and lexical features proposed in [20], that appears to be the state-of-the-art metrics so far. We removed the ones strongly correlated with the length of the text, as our dataset presents a potential bias of categorical distribution over the text length. We ended up with 30 syntactic and lexical features, 300 features from Glove and 17 conceptual features. The classifier has the same architecture as those trained before.

The results for the test are presented in table 5, while the Precision-Recall curve is illustrated in Figure 5. With high scores in both precision and recall, this model seems to be suitable to assist teachers in their assessment of complexity.

6. CONCLUSION AND PERSPECTIVES

At the core of several learning related activities, the assessment of complexity is a task of importance. This topic has been broadly studied through the structural analysis of texts, with the design and evaluation of lexical, syntactic or morphological measures. The consideration of semantic metrics, however, is still scarce. Recently, word embedding techniques have demonstrated their promising potential to design powerful predictive models of semantic complexity, but lack explainability. In order to overcome this obstacle, we proposed an approach based on the exploitation of existing knowledge graphs to generate a graph representa-

tion of a text, whose concepts are exposed and related each other through their abstractions. We suggested 17 metrics computed from this concept graph to highlight intelligible information about the semantic complexity of the text.

We evaluated our proposition within the context of learners' productions for a European certification of English as a foreign language. We observed that a word embedding based classifier still tends to surpass a model relying solely on our features. Nevertheless, a classifier that uses these two sets of features together outperforms significantly the previous ones. At last, we proposed a classifier using these semantic metrics but also syntactic and lexical features. Tested in our context of learners' evaluation, its performances seem to make it suitable to assist human examiners in their tasks.

Eventually, we found, at the time of writing, a similar approach to ours, based on the DBpedia knowledge graph to measure conceptual complexity [30]. Authors used concepts extraction in the context of text simplification. Although not based on a concept graph as we did, the metrics they proposed may be also relevant for our domains of application. We will then integrate them to our model shortly. While first results obtained are promising, we have to dig into the analysis of each metric we suggested, in order to evaluate their power of discrimination regarding the conceptual complexity of the features we proposed. At a longer term, it will offer opportunities to consider a proactive usage on users to assist them in their learning activities. Assessing complexity is also of importance for learning resources indexing, to provide useful recommendations. Since this domain of application is different from the present context of study, we will consolidate a dataset of learning objects and then reproduce the experimentation to evaluate how our approach generalizes to other tasks.

ABSTRACT

The role of affective states in learning has recently attracted considerable attention in education research. The accurate prediction of affective states can help increase the learning gain by incorporating targeted interventions that are capable of adjusting to changes in the individual affective states of students. Until recently, most work on the prediction of affective states has relied on expensive and stationary lab devices that are not well suited for classrooms and everyday use. Here, we present an automated pipeline capable of accurately predicting (AUC up to 0.86) the affective states of participants solving tablet-based math tasks using signals from low-cost mobile bio-sensors. In addition, we show that we can achieve a similar classification performance (AUC up to 0.84) by only using handwriting data recorded from a stylus while students solved the math tasks. Given the emerging digitization of classrooms and increased reliance on tablets as teaching tools, stylus data may be a viable alternative to bio-sensors for the prediction of affective states.

Classification, Affective Computing, Stylus, Biometric Sensors

1. INTRODUCTION

Affective states are psycho-physiological constructs used to characterize the emotions (short-lived) and moods (long-lived) that arise and are experienced while individuals are engaged with a stimulus. Affective states play an important role in the educational context and can directly influence a student's learning gain [9, 26, 10]. For example, learning outcomes have been found to decrease if frustration is persistent during problem solving, whereas overcoming a state of frustration can have a positive effect on learning [10].

Previous research has investigated the relationship between affective states and learning performance by attempting to detect the diverse emotions that occur during learning. The logic behind this approach is that, depending on the emotion of a student, appropriate actions can be taken in order to assist students during learning (e.g., adapting task elements in the case of intelligent tutoring systems (ITS) and self-regulation by providing affective feedback).

Previously, a wide range of data sources have been used to measure and predict affective states in the learning context including audio and video [32], interaction data [21, 14] and bio-sensors [8, 4]. Systems that rely on the analysis of audio (e.g., speech) and video (e.g., facial expression) data [32] cannot guarantee full anonymity and are subject to privacy issues. Given these limitations, researchers have attempted to derive the affective state of individuals based on interaction data which contain log data of the user's interaction with the learning system, such as input and error behavior, timing and help calls [21, 14]. Although large and powerful interaction data sets can be easily collected especially in online environments, the features are typically dependent on the learning domain and on the specific learning system. Attempts towards a cross-domain or cross-system engagement model have been presented (e.g., for learning spelling and math [18]), but these generalized methods typically have a lower accuracy as domain-specific features. Data from bio-sensors (e.g., measuring muscle activity [8] and heart rate [4]) have also been used to predict emotions. However, most of these devices are typically restricted to lab settings, expensive and difficult to operate, and somewhat intrusive. Recently, a variety of portable and low-cost bio-sensor devices have become available (e.g., Shimmer GSR+ and Polar H10). These devices have the potential to transform education research because they can be used to monitor a learner's physiological state at home or in a classroom.

In this paper, we explore a low-cost mobile setup to detect the affective state of students. Our goal is a system to detect affective states that is cheap and easy to operate, can be used outside a lab setting, is non-intrusive, and minimizes potential issues related to privacy. We consider bio-sensor data from skin conductance, heart measures, and skin temperature. In addition, and in contrast to previous work in

Rafael Wampfler, Severin Klingler, Barbara Solenthaler, Victor Schinazi and Markus Gross "Affective State Prediction in a Mobile Setting using Wearable Biometric Sensors and Stylus" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 198 - 207

the field of learning systems, we also evaluate handwriting data recorded by a stylus to predict the affective state of students. Here, we use the fact that tablets bundled with a stylus are becoming increasingly available in households and classrooms and are inherently non-intrusive and mobile.

We propose a generic pipeline in which we process the data from the bio-sensors and stylus in order to extract a set of features for each of the sensors. We then use a classification model to predict the current affective region in the valence-arousal space of emotions [29]. Valence describes how much an emotion is perceived as positive or negative and arousal represents the intensity of the emotion. Our method allows researchers to define arbitrary areas of interest in the valence-arousal space, and can be applied to a wide range of applications and questions of interest. We evaluated our method by applying it to a math problem solving scenario in which participants provided answers in unstructured handwriting on a tablet device. Best performance was reached when data from all sensors was used for prediction (0.88 AUC). Interestingly, we reached a comparable performance using only the data acquired by the stylus (0.84 AUC). These results suggest that a simple tablet with a stylus can be sufficient to reliably predict a student's emotional state. Finally, we also explored whether the affective state model could be generalized over domains. For this purpose, we applied the trained model to a passive setting with picture stimuli leading to a performance of 0.68 AUC.

2. RELATED WORK

Affective States and Interaction Data. Due to their influence on learning gain, affective states play an important role in education in general and in particular during math learning [27, 21]. Boredom was shown to negatively influence the learning gain [9, 26], while engaged concentration can improve the learning outcome [9]. Interestingly, frustration and confusion can positively affect learning in case the student is able to resolve these states [10]. One line of research tries to predict these affective states based on logged user interactions only. Frustration, boredom, engaged concentration and confusion have been successfully predicted using interaction data for math tutoring systems [21, 14]. On the other hand, valence and arousal have been predicted using mouse and keyboard interaction data from writing compositions in free text [31]. Moreover, generalized models have been proposed, such as an engagement model for two different learning domains and tutors (spelling and math) [18]. Based on such automatically predicted affective states, different intervention strategies have been explored. An automatic student-centered affect-aware feedback loop was shown to increase the learning gain [14] while other work explored how teachers can provide better interventions based on real-time information about the evolution of student's affective states [11].

Biometric Sensors. Biometric sensors provide an objective measure of the physiological reactivity of users engaging with a learning environment while minimizing interference with the actual task [19, 4, 17, 30]. Indeed, educational research has investigated the effectiveness of a variety of physiological signals used to infer affective states. Electrodermal activity, skin temperature, and heart rate were generally found to be good predictors of emotions [19, 17,

30] and mind wandering [4] across different tasks including math learning [17, 30], scientific text reading [4] and audio, visual and cognitive stimuli in general [19]. However, these previous works mainly focused on expensive, high quality sensors to provide medical grade accuracy for the measurement of physiological signals. In contrast, we focus on an affective tutor that can be used in learning systems, hence we gather such data in a non-intrusive and easy to use way.

Stylus. Predicting affective states based on stylus data is still a relatively new research topic. Likforman-Sulem et al. [24] predicted anxiety, depression and stress based on figure drawings and writing given words. Fairhurst et al. [12] conducted an experiment for predicting stress and happiness by letting participants writing down a given list of words and describing a visual scene in own words. Instead of predicting a fixed set of affective states, our approach can capture different affective regions which can be defined according to the researchers need. Our approach is not restricted to copying predefined sentences and figures but works with arbitrary handwriting and drawing. To our knowledge, this is the first work to leverage stylus data in order to predict the affective state of a student during math solving.

3. METHOD

We present a classification pipeline that automatically predicts affective states based on low-cost and mobile bio-sensor and stylus devices. Our pipeline assumes that we have access to reports on affective states of users based on the circumplex model of affects [29]. The circumplex model is a two-dimensional model representing affective states in terms of valence and arousal. The classification task then amounts to classifying regions within this space using a combination of signals from bio-sensor and stylus devices. For this purpose, we build a generic affective predictor (Figure 1). Recorded stylus and bio-sensor data are preprocessed and the relevant features are extracted to train a classification model for the specific affective regions. We design our predictor to work unobtrusively in the background of any ITS.

3.1 Input Signals

During the task solving process bio-sensor and stylus data are recorded.

Electrodermal activity (EDA). EDA is an indicator of the emotional state of a person reflected by the variation in the electrical characteristics of the skin as a result of sweating [2]. EDA is quantified by measuring the amount of current flowing between electrodes attached to the skin. Changes in affective states can lead to subtle variations in the level of sweat that can be detected as the changes in the current. Typically, the EDA signal is decomposed into tonic (low frequency) and phasic (high frequency) components.

Interbeat Intervals (IBIs). IBIs are the time intervals between consecutive heartbeats in normal heart function. This natural variation is also known as heart rate variability (HRV). The heart rate (HR) can be easily computed as the inverse of the IBI averaged over a certain time window.

Skin Temperature (ST). ST measures the thermal response of human skin. Vasoconstriction (e.g., provoked by

Figure 1: The classification pipeline. Stylus and bio-sensor data are gathered during task solving processes. After preprocessing the signals, features are extracted and used to classify the affective regions of interest.

an affective state) can result in an increase in blood flow and a consequent increase in ST [19].

Stylus. Tablet devices often come equipped with stylus pens as accessories that can provide precise and pressure-sensitive input. Stylus data consists of the applied pressure during writing and the pixel positions of the written text. From these measurements, handwriting characteristics related to time and ductus can be calculated.

3.2 Preprocessing of Signals

During preprocessing, the raw input signals are filtered in order to detect artifacts from movement and muscle contraction. The signals are also corrected for differences between individuals using baseline recordings for each individual.

Artifact detection. We follow the procedure outlined by Greco and colleagues [15] to decompose the EDA into tonic, phasic and an additive white Gaussian noise component with a convex optimization approach that accounts for signal filtering and detrending. For IBIs, detrending is not necessary in the preprocessing [36], and we use the criterion beat difference for artifact detection [16].

Baseline correction. Similar to previous work [30, 17], we collect baseline data for all sensors in order to account for individual differences in stylus and bio-sensor signals related to writing habit, ambient temperature and dryness of the skin. Baseline data is collected while individuals remain in a relaxed state (e.g., watching a nature video). We search for the minimum value of each bio-sensor signal during the relaxation phase over a 10 seconds window using a sliding window approach to be robust against outliers. Due to possible signal lags, we search the minimum for each signal separately. We then normalize the bio-sensor data by subtracting the feature values calculated over the corresponding 10 seconds interval of the baseline from the actual feature values computed during task solving. Stylus data is normalized by subtracting a baseline for all features computed over handwriting of an English sentence.

3.3 Feature Extraction

In the proposed pipeline, we extract several different feature types from the stylus and bio-sensor signals. Where appropriate, we compute basic statistics for these features types including the mean, standard deviation (SD), minimum and maximum and the linear trend (slope of a fitted linear regression line). A summary of all extracted features is presented in Table 1.

EDA. For EDA, we decompose the signal into phasic and tonic components and calculate standard statistics (i.e., mean, SD, min, max, slope). For the phasic component, we also calculate the area under the curve (AUC) [3] and the number of peaks using zero-crossings of the smoothed gradients of the signal [19]. Based on the extracted peaks, we further compute amplitude statistics (i.e., mean, min, max) [38].

IBI. From the IBI recordings, we extract temporal and frequency features. In the temporal domain, we calculate the percentage of successive IBIs that differ by more than 50 milliseconds (pNN50) and 20 milliseconds (pNN20) as well as the SD and root mean square of successive differences between adjacent IBIs (SDSD and RMSSD) [34, 25]. For the frequency domain, it is well known that the distribution of spectral power gives an indication of physiological activation [3]. Therefore, we extract a feature related to the high frequency (HF) band of 0.15-0.40 Hz by a Fast Fourier transform of the cubic spline interpolated signal [34, 25]. Based on the IBIs, we compute the heart rate for which we extract several standard statistics (i.e., mean, SD, min, max, slope).

ST. We extract several statistics (i.e., mean, SD, min, max, slope) from the temperature signal [38, 35].

Stylus. From the stylus data, we derive features related to the pressure applied by the pen as well as timing and location information. Previous research has successfully employed these features to predict affective states [24, 12]. From the pressure data, we compute standard statistics (mean, SD, max, min) per stroke and average these over an entire task. Additionally, over each task we compute the slope of a linear regression fit to the pressure values and the statistical skewness of the pressure distribution. We also compute standard statistics (i.e., mean, SD, max, min, slope) of the speed and acceleration of the strokes. For the handwriting data, we discriminate between the actual writing process and the think time while completing the task [24]. During writing there are always small time gaps between strokes which cannot be attributed to thinking but belong to the writing process itself. Because writing patterns are different for every user, we infer an individual threshold for each user to distinguish if the time between two strokes belongs to thinking or to the actual writing process. We chose this threshold as the 80 % cut-off value of the distribution of the time between the strokes over the stylus baseline (cropping the right tail of the distribution). Based on this threshold, we derive a feature measuring the percentage of writing (i.e., the time spent in the writing process). Additionally, we compute the

statistics (i.e., mean, SD, max, min) on the speed between consecutive strokes having time differences below threshold (writing process) and on the distance between strokes having time differences above threshold (thinking).

Table 1: Extracted bio-sensor and stylus features. For each signal, the features are sorted according to their importance (based on our experiments). The 10 most predictive features are highlighted in bold. SD refers to the standard deviation.

Signals	Features
EDA	Phasic AUC, Phasic Mean, Tonic SD, Tonic Max, Tonic Mean, Tonic Min, Phasic SD, # Phasic Peaks, Tonic Slope, Max Phasic Peak Amplitude, Min Phasic Peak Amplitude, Phasic Slope, Mean Phasic Peak Amplitude
Heart	IBI SDSD, IBI RMSSD, IBI SD, IBI pNN20, HR Mean, IBI High Frequency, IBI pNN50, IBI Mean, HR Min, HR Max, HR SD, HR Slope

Stylus	#Strokes/Mean Speed, Mean Distance between Strokes, Max Distance between Strokes, SD Distance between Strokes, Mean Pressure, Max Pressure, Mean Stroke Acceleration, Max Stroke Acceleration, Max Stroke Speed, Max Speed between Strokes, Mean Speed between Strokes, SD Speed between Strokes, SD Stroke Speed, SD Stroke Acceleration Excluded ¹ : %Writing, {SD, Slope, Skewness} Pressure, {Mean, Min, Slope} Stroke Speed, {Min, Slope} Stroke Acceleration, Min Speed between Strokes, Min Distance between Strokes, #Strokes/Minute

¹ Excluded due to our experimental setup (see Section 5.1)

3.4 Classification

To train our classification algorithms ground truth is built by defining arbitrary non-overlapping regions of interest in the two-dimensional valence and arousal space based on the affective labels which can be gathered, for example, through self-reports or expert labelers. We then use a classification model to predict the affective region an individual is likely to be in during task solving based on the recorded bio-sensor and stylus data. Before applying the classification algorithm, we standardize all features to have zero mean and unit variance. We propose the usage of four different classifiers (i.e., Random Forest, Support Vector Machine, k-Nearest Neighbors and Gaussian Naive Bayes). We select these classifiers because they are among the most widely used in machine learning and have shown to provide good results on bio-sensor and stylus data [37, 24, 13]. All models are evaluated using leave-one-user-out cross-validation which ensures that data from the same user is not in the testing and training set at the same time. Hyperparameter optimization is performed using nested cross-validation and randomized search.

4. EXPERIMENT

We conducted a controlled lab experiment with 88 participants in order to test our pipeline. In the experiment, we recorded bio-sensor and stylus data while participants solved

approximately 40 math tasks chosen to trigger different affective states. The math tasks were chosen because they are an integral part of the educational curriculum. However, instead of relying on a math based ITS, we have designed specific math tasks to increase the probability of evoking a wider range of affective states.

4.1 Experimental Setup

Participants. We recruited 88 participants (45 female) between ages of 18 and 29 (mean = 22.1, SD = 2.0) from 10 different engineering and natural science departments of the second and third year of the Bachelor program of an university. We excluded participants suffering from cardiovascular pathologies, smokers, and participants suffering from evident mental pathologies (score > 4 in the Patient Health Questionnaire [22]). In order to control for external factors, we kept the humidity and room temperature at an average of 21.7 °C (SD = 0.59 °C) and 32.6 % (SD = 5.3 %), respectively. Figure 2 presents the experimental setup.

Sensors. We measured EDA and wrist acceleration using a Shimmer GSR+ device. To test the accuracy of the device, we compared its measurements with a state of the art ADInstruments PowerLab 8/35 device (connected through the ADInstruments FE116 GSRAmp signal amplifier) over a 23 minute recording of an user watching a nature video and picture stimuli. Results revealed a strong and significant cross-correlation value of 0.96 (p -value < 10^{-100}) between the two signals. These results suggest that the smaller, mobile and more affordable Shimmer GSR+ device may be sufficient to detect changes in affective states. During the experiment, the Shimmer GSR+ device was worn on the non-dominant hand with the electrodes placed at the proximal phalanx of the index and middle finger [7]. Data was recorded at a sampling rate of 100 Hz. As part of the Shimmer GSR+ setup, we also attached an optical pulse sensor providing a photoplethysmogram signal on the ring finger. However, photoplethysmogram data was of poor quality and consequently discarded from analysis. Prior to electrode attachment, we asked participants to wash their hands with lukewarm water [5]. Heart activity was measured using a Polar H10 chest belt. The Polar H10 belt provides IBIs and post-processed heart rate data by monitoring electrical changes on the surface of the skin. A predecessor of this device (Polar H7) was shown to provide accurate data when compared to an expensive lab device (Cosmed Quark T12x system) [28]. We recorded the skin temperature using the infrared thermopile sensor of the Empatica E4 device (sampling rate = 4 Hz; resolution = 0.02 °C). Since the sensor was attached to the dominant hand (used for writing during the tasks), other signals that the wristband can provide (EDA and blood volume pulse) were heavily affected by motion artifacts and discarded from the analyses.

During the experiment, participants interacted with a Huawei MediaPad M2 10.0 running Android 5.1 to solve the different math tasks. All interactions with the tablet were conducted with a Wacom Bamboo Ink stylus at an average sampling rate of 250 Hz (SD = 25 Hz) and with 2048 levels of pressure sensitivity. The signals from the bio-sensor devices were streamed to the tablet using the Bluetooth Low Energy protocol. We also recorded the behaviour of participants with the front camera of the tablet and a GoPro HERO3 camera.

Figure 2: A participant completing the math tasks. A) During each session data is recorded from different devices. (1) An Empatica E4 recording skin temperature on the dominant hand. (2) A Shimmer GSR+ measuring skin conductance and wrist acceleration on the non-dominant hand. Participant behaviour was recorded by (3) the tablet front cam and (4) a GoPro HERO3. All interactions with the tablet were conducted with a stylus (5). Participants also wore a Polar H10 chest belt (not visible in the image) for recording heart activity. B) The task interface allows participants to write solution paths directly onto the screen (the stylus pressure is color-coded for visualization purposes only).

4.2 Experimental Procedure

For measuring the affective states of the participants we have used the self-assessment manikin (SAM) [6]. The SAM provides valence and arousal labels on a scale from 1 (most negative, lowest arousal) to 9 (most positive, highest arousal). For triggering the affective states we have used math tasks and pictures from the International Affective Picture System (IAPS) [23]. The IAPS is a database of 1182 pictures typically used in emotion research and has been standardized in terms of valence and arousal based on SAM ratings. We used the IAPS to investigate whether the affective model for the math tasks generalized to passive tasks, such as watching pictures (Section 5.6). As such, the set of IAPS pictures presented to the participants was sampled to cover similar affective regions as those expected to be evoked by the different math tasks.

An overview of the study procedure is presented in Figure 3A. The experiment lasted an average of 90 minutes for each participant. Upon arriving at the lab, participants completed a demographics questionnaire and were given an oral overview of the procedure. This included an explanation of the SAM questionnaire based on 4 example pictures from the IAPS presented on paper. Next, participants started working independently on the tablet by first watching a 7 minute nature video (bio-sensor baseline), followed by the stylus baseline that consisted of writing an English sentence with the stylus. Participants were then presented with 40 pictures from the IAPS in random order. Each picture was shown for 10 seconds and was directly followed by the SAM rating (valence and arousal) and a 10 second fixation cross. In total, we collected 3400 ratings from all participants. After rating the IAPS pictures, participants were asked to watch the nature video one more time before completing the math tasks. Before finishing the experiment, participants completed a paper questionnaire about their overall mood, comfort level while wearing the sensors, nervousness and sweating level.

4.3 Experimental Tasks

To trigger different affective states, we have created three different math task conditions by varying the difficulty level,

available time for completion and monetary reward of the task. These types of manipulations were shown to be effective at eliciting different affective states in reading comprehension [4] and math tasks [32].

Task design. The math tasks were taken from an ACT data set [1] that provided difficulty ratings from 0.12 (most difficult) to 0.96 (simplest). We conducted a pilot study (exact same conditions, 11 participants) to get an indication of the time needed to solve the different tasks. Based on this timing information and the tasks from the ACT data set we generated the following three conditions.

1) *Repetitive condition.* For the *repetitive condition* we created random variants (by substituting the numerical values in the task) of two easy tasks from the ACT data set (difficulty = 0.76 and 0.83). The time available to solve each task was set between 60 and 75 seconds at random. This provided participants with more than sufficient time to come up with a solution for each task. Correctly solving a task in the *repetitive condition* granted only a minor monetary reward (+CHF 0.2) and a minor penalty (-CHF 0.2) for incorrect solutions. The *repetitive condition* was designed to trigger emotions such as boredom and fatigue.

2) *Challenge condition.* For the *challenge condition* we selected math tasks from the ACT data set with medium difficulty (difficulty $\in [0.58, 0.69]$) and provided participants with a larger monetary reward (+CHF 2) for correct solutions and the same small penalty as the *repetitive condition* (-CHF 0.2) for incorrect solutions. Participants were provided with sufficient time to solve the tasks based on data from the pilot study (min = 53 seconds, max = 93 seconds). The *challenge condition* was designed to provide diversified tasks for a more engaging and interesting experience, while the larger monetary reward provided a bigger incentive (higher-stakes) for participants to perform well with relatively small penalty in case of mistakes.

3) *Overchallenge condition.* For the *overchallenge condition*, we selected the math tasks with high difficulty in the

Figure 3: Overview over the different parts of the study. A) Overall experimental procedure. B) Changes in valence and arousal for one participant in relation to task type and answer.

ACT data set (difficulty $\in [0.25, 0.53]$). Participants received small monetary rewards for correct solutions (+CHF 0.2) and a large penalty (-CHF 2) for incorrect solutions. The time to solve each task was set to be insufficient for most participants based on data from the pilot study (min = 25 seconds, max = 51 seconds). The *overchallenge condition* was designed to provide a frustrating and annoying experience to participants.

The math tasks were presented in six blocks (2 in each condition) each containing a different number of tasks (*repetitive condition* 13 tasks, *challenge condition* 5 tasks, *overchallenge condition* 6 tasks). A similar block design for math tasks was already applied in previous work [32]. Moreover, we believe that a sequence of tasks is necessary to trigger an affective state. The first 3 blocks presented were randomly sampled. However, the succeeding 3 blocks were fixed to the same order as the first 3 blocks (but contained different tasks). In addition, the maximum time for each block was limited to 5 minutes to ensure that the math part of the experiment does not go over 30 minutes. After each block, a fixation cross was shown for 30 seconds to reduce potential carry-over effects of affective states. At the end of each math task, participants were asked to fill in the 9-point SAM scale to report their current valence and arousal level (in total, we have collected 3026 ratings from the participants). Figure 3B depicts the changes in the valence and arousal ratings for one participant in relation to the block type and task answer (correct vs. incorrect). We see that for the repetitive tasks, valence and arousal are decreasing over time leading to a shift towards boredom. Additionally, for incorrectly solved tasks, valence drops and arousal tends to increase. After the repetitive blocks we see a decrease in valence and an immediate steep increase in arousal that may be attributed to the increase in difficulty from the repetitive block to the overchallenge block. On average participants finished with CHF 44.3 (min = CHF 22.2, max = CHF 62.8). At the end of the experiment, each participant was compensated with a minimum of CHF 40.

Math task interface. Participants were asked to provide a solution path for every task anywhere on the screen and then to select their answers from 5 multiple-choice alternatives (see Figure 2B). Participants received immediate feedback

on whether their answer was correct. A timer located on the top right corner of the interface informed participants about the time left to respond and started to blink when less than 10 seconds remained. When the time was up and the participant did not submit a solution, the answer was considered wrong. The cumulative amount of money earned was displayed on the top left of the interface.

5. RESULTS

We compared different versions of our classification pipeline using only a subset of the sensors with a focus on the difference between stylus and bio-sensors. All results are based on Random Forest (using 500 trees, balanced class weights and hyperparameter optimization using randomized search with 100 iterations) given that this was the best performing classifier. In order to measure the performance of our classifiers, we have used accuracy (chance level = $1/\#$ classes) and micro-averaged area under curve (AUC) of the receiver operating characteristic (ROC) curve (chance level = 0.5), which aggregates the contributions of all classes to compute the average metric. Because both metrics are affected by class imbalance, we have also considered the macro-averaged AUC (chance level = 0.5) which is the average of the class-wise AUCs giving each class the same weight. To derive the SD for each metric, we employed an additional 10-fold cross-validation.

5.1 Study Validation

Our study was designed to trigger affective states across the entire valence-arousal space. As a first step, we investigated if our study design worked by examining if the different parameters acted as intended. In our task design we varied task difficulty, monetary reward and the available time for task completion. We have performed a per task Kendall's tau correlation analysis between these 3 parameters and the arousal and valence ratings of the participants. For the task difficulty and the percentage of remaining time, we have found high correlations for both valence (-0.2 ; p -value $< 10^{-59}$ and 0.22 ; p -value $< 10^{-80}$) and arousal (0.27 ; p -value $< 10^{-102}$ and -0.27 ; p -value $< 10^{-117}$). Participants shifted towards frustration (decreasing valence and increasing arousal) with increasing task difficulty or with a reduction in the time remaining to complete the task. In-

Figure 4: Heat maps showing the distribution of the participants' ratings on the math tasks. The red rectangles represent the different regions. A) 5 regions automatically chosen using k-means clustering. B) Three regions manually selected. C) Six regions manually selected.

terestingly, the effect size on valence and arousal is almost identical. In contrast, monetary reward appears to have a much larger effect on valence (0.47 ; $p\text{-value} < 10^{-295}$) than on arousal (-0.06 ; $p\text{-value} < 10^{-4}$). Altogether, it appears that our tasks worked as intended. Accounting for potential superficial correlations (e.g., task duration) is an important part of our study design. We found a significant Kendall's tau correlation between the task duration and the user ratings of 0.17 ($p\text{-value} < 10^{-48}$) and -0.11 ($p\text{-value} < 10^{-22}$) for arousal and valence, respectively. Because we have extracted the stylus features over the whole tasks, we have excluded all features having a significant Spearman correlation to the task duration (features greyed out in Table 1).

5.2 Data Analysis

Input Signals. Given that we detected a very low amount of artifacts across participants (EDA = 0.015% and IBI = 0.71%), we refrained from removing them from the analysis. Visual inspection of the ST recordings revealed a slow linear increase of the temperature over the course of a participant's session. This change in temperature may be due to the skin warming up under the wristband and independent of the affective state of the participants. We removed this linear trend from all measurements by subtracting the result of a linear least-squares fit to the signal. We did not observe any other artifacts for ST. The bio-sensor features listed in Table 1 have been computed using a window of 10 seconds since the minimum task duration was 10 seconds. For the stylus features, we have used an implicit window over the entire task. In addition, we have excluded all data points having at least one missing value.

Clustering of Ratings. Figure 4 presents the distribution of the participants' ratings in the valence-arousal space (dark and light blue refers to a high and low number of data points, respectively). A v-shape is visible with most ratings being made at a valence and arousal level of 7 and 5, corresponding to a positive medium intense state (e.g., interest). Several ratings were made at the extremes (top left and top right) of the valence-arousal space corresponding to states of distress and excitement that are associated with very good and very poor performance. To uncover the underlying clusters in the data, we have applied k-means

clustering in this two-dimensional valence and arousal space. Using the Bayesian information criterion, we found an optimal number of 5 clusters. We defined region boundaries (shown by the red rectangles in Figure 4A) as the arithmetically rounded value of the centroid of each cluster plus and minus the standard deviation of the participants' ratings in the corresponding cluster. We observed that the regions are all of equal size and cover the area of the v-shape. Based on Russell's [29] and Scherer's [33] categorization we identify the following regions, their sizes and corresponding affective states: Region R1 (213 data points; frustrated, annoyed), region R2 (284; bored, taken aback), region R3 (965; attentive, serious), region R4 (861; expectant, confident), region R5 (295; excited, triumphant). Together, it appears that the math task covered a broad range of affective states relevant for learning and that positive states (R3, R4, R5) dominate.

5.3 Classification Performance

Figure 5A and Table 2 present the predictive performance of the model based on the 5 defined regions. Using all sensors, the model achieved an accuracy of 65% (chance level = 20%). Here, the slightly lower value for the macro-averaged AUC (0.83) compared to the micro-averaged AUC (0.88) may be related to class imbalance. Figure 5C depicts the confusion matrix based on all sensors. The matrix shows that regions R1 and R2 are more difficult to predict than the other regions. This may be due to the lower number of data points collected for these regions. As expected, the larger the distance between the regions, the easier it is for the model to discriminate between them.

Feature Importance. Table 1 presents the 10 most important features (in bold). The features are sorted according to their relative importance which we computed using permutation feature importance (permuting each feature 100 times and measuring the mean decrease in micro-averaged AUC). We obtained the same relative feature importance ordering using the Gini importance measure. EDA and heart measures provided 3 out of the 10 most important features and stylus features contributed with 4 of the most important features. There were no ST features among the top ten features. Regarding the heart measures, the features related to IBIs were more important than HR features. An

interesting observation can be made for the stylus features. Features related to the distance between strokes appear to be more important than speed between stroke features indicating that the spread of writing attributed to thinking (i.e., how the writing space is covered) provides more information than the actual writing behaviour.

5.4 Sensor Comparison

Bio-Sensors. If we consider the individual sensors (Figure 5B), ST performs substantially worse (-0.11 AUC) compared to EDA (0.80 AUC) and heart rate measures (0.81 AUC). The combination of all the bio-sensors (Figure 5A) provides only marginal performance improvements ($+0.05$ AUC) compared to the individual sensors.

Stylus. Our most important finding is that the stylus performs equally well as the bio-sensors (Figure 5B), rendering the data from the bio-sensors redundant and unnecessary for the prediction of affective states. The performance of the stylus is only marginally inferior (-0.02 AUC) when compared to the combination of all bio-sensors. In contrast, the combination of the bio-sensors and the stylus achieves a slightly higher performance ($+0.02$ AUC) compared with the bio-sensors and stylus alone (Figure 5A). This might be an indication that they may contain complementary information, although the difference appears to be small.

5.5 Affective Region Analysis

In order to investigate the ability of our pipeline to predict different affective regions based on the recorded bio-sensor and stylus data we have defined two additional coverings of the valence and arousal space (Figure 4B and 4C). Based on Russell [29] and Scherer [33] we have manually defined specific regions associated with frustration (annoying; region R6, 185 data points), boredom (taken aback; region R7, 199) and interest (engaged concentration, flow; region R8, 720) as shown in Figure 4B. Being able to distinguish these 3 regions is important in education due to their impact on learning gain [9, 26, 10]. To cover the valence and arousal space evenly, we have manually defined the 6 regions shown in Figure 4C, dividing arousal in two and valence in 3 components (The number of data points from region R9 to R14 are 287, 154, 134, 852, 432 and 506). The results for both space partitionings are listed in Table 2 (note that chance level for the accuracy is 33 % for 3 regions and 16.66 % for 6 regions). The performance of the classification of 3 regions outperforms the one for 5 and 6 regions in terms of accuracy. On the other hand, when taking into account the AUC, there is no substantial difference in performance between the different coverings. This difference between accuracy and AUC stems from the fact that predicting only 3 regions is a much easier task than predicting 5 or 6 regions. This is in line with the finding that the accuracy for predicting 5 regions is slightly higher than for 6 regions. Nevertheless, we can conclude that we have seen that our approach is able to provide good results for 3 different coverings. Thus, we come to the conclusion that our pipeline is rather flexible being able to handle different regions in the valence-arousal space. Compared to previous work relying on fixed affective states, our approach has the advantage that the regions do not have to be pre-defined allowing for much more flexible use.

Table 2: Performance of Random Forest on the math data for different signals and regions. AUC_{micro} and AUC_{macro} represent micro-averaged and macro-averaged AUC, respectively. The chance level for accuracy is $1/\#$ regions and for AUC it is 0.5. The standard deviations are given in brackets.

Regions	Signals	AUC_{micro}	AUC_{macro}	Accuracy
k-means (5 Regions)	EDA	0.80 (0.02)	0.75 (0.03)	50 % (4 %)
	Heart	0.81 (0.01)	0.73 (0.01)	52 % (2 %)
	Temperature	0.69 (0.03)	0.59 (0.03)	37 % (4 %)
	Stylus	0.84 (0.01)	0.76 (0.02)	59 % (2 %)
	Bio-Sensors	0.86 (0.01)	0.81 (0.02)	60 % (2 %)
	Bio-Sensors & Stylus	0.88 (0.01)	0.83 (0.02)	64 % (2 %)
Manual (3 Regions)	EDA	0.81 (0.02)	0.69 (0.04)	66 % (2 %)
	Heart	0.79 (0.02)	0.66 (0.03)	62 % (3 %)
	Temperature	0.76 (0.01)	0.60 (0.04)	60 % (3 %)
	Stylus	0.83 (0.02)	0.72 (0.02)	67 % (3 %)
	Bio-Sensors	0.84 (0.01)	0.76 (0.03)	67 % (1 %)
	Bio-Sensors & Stylus	0.87 (0.01)	0.80 (0.02)	67 % (2 %)
Manual (6 Regions)	EDA	0.80 (0.02)	0.72 (0.03)	46 % (3 %)
	Heart	0.78 (0.01)	0.72 (0.02)	44 % (2 %)
	Temperature	0.70 (0.02)	0.61 (0.02)	35 % (3 %)
	Stylus	0.81 (0.01)	0.75 (0.02)	48 % (2 %)
	Bio-Sensors	0.85 (0.02)	0.80 (0.02)	57 % (4 %)
	Bio-Sensors & Stylus	0.87 (0.02)	0.83 (0.03)	61 % (3 %)

5.6 Model Transfer

In addition to the math tasks, we have also gathered bio-sensor data as well as valence and arousal ratings from the participants while they observed pictures from the IAPS. We have used this data to investigate our model's capacity to generalize to more passive tasks, such as looking at pictures. To predict the affective regions of interest, we applied our model trained on the bio-sensor data recorded during math task solving to data collected while participants viewed and rated the set of IAPS pictures. When we consider the 5 different regions (Figure 4A), the model's accuracy reaches 39 % (chance level = 20 %, $AUC_{micro} = 0.68$, $AUC_{macro} = 0.64$). When we train and evaluate a model directly on the picture data, we achieve a slightly better classification performance (accuracy = 42 %, $AUC_{micro} = 0.74$, $AUC_{macro} = 0.66$). There may be several reasons behind the suboptimal performance when predicting affective states during the picture task. These include sociocultural aspects when rating emotions based on pictures (e.g., rating how it is expected), old and low resolution pictures from the IAPS data set, media influence desensitizing participants to the content of the IAPS, and the fact that the math and picture domains are very different. Together these initial results indicate that building a general predictor of affective states might be possible, but further experiments are necessary.

6. CONCLUSION

In this paper we presented a generic pipeline for predicting affective regions of interest using bio-sensor and stylus data. We validated our pipeline for the case of math solving tasks and demonstrated that our pipeline can accurately predict various regions in the valence-arousal space (up to 0.88 AUC). In addition, we have compared different input signals with each other. The performance of the Shimmer GSR+ and Polar H10 have been on the same level (up to 0.81 AUC). Moreover, we found that the classification performance using only stylus data is comparable to the classification performance based on the bio-sensors. Taking into account the emerging digitization of education and the spread of tablets in schools and private households, these results

Figure 5: ROC curves and micro-averaged AUC scores for 5 regions chosen by k-means clustering for (A) the bio-sensors, stylus and the combination of bio sensors and stylus and (B) the individual bio-sensors & stylus. (C) The confusion matrix is computed by using the combination of bio-sensors and stylus.

make the stylus a preferred alternative to bio-sensors for measuring affective states in classrooms. Using bio-sensors in classroom settings can be cumbersome and costly as it requires the purchase and synchronization of several devices. In contrast, systems that depend on a stylus only are cheaper than systems relying on bio-sensor devices, and styluses often come bundled with mobile devices, such as tablets or smartphones. In addition to being cheaper and more ubiquitous, styluses are easier to setup (e.g., no attachment of electrodes, no motion artifacts) and less intrusive. Furthermore, stylus data is not only restricted to digital devices but can also be recorded using digital pens. Finally, we have demonstrated the possibility of a generalized model for predicting affective states by applying the model trained on the data from the math tasks (active part) to pictures from the IAPS (passive part) reaching a performance of 0.68 AUC.

There are some potential limitations to the approach presented here. First of all, the setup is restricted to a lab environment and the population of Bachelor students may limit generalization to students at other levels. We are optimistic that our approach also works outside a controlled setting and for a broader population. Participants reported that the setup was comfortable and that they could act in a natural way. In addition, we assume that given a proper baseline correction the signals are also predictive for a heterogeneous group of people. Another limitation is the restriction to math tasks. Similar to bio-sensor data, we believe that handwriting data carries affective information independent of the task. Thus, we expect our approach to work also in other domains involving handwriting, such as solving exercises for different school subjects and writing essays.

Future research from our lab will test and refine our pipeline for multiple domains. Potential refinements include using non-linear IBI features and frequency features for skin temperature. Additionally, an in depth analysis of handwriting that takes into account the slant of the handwriting could further improve the classification performance. Another interesting direction would be to make use of large existing bio-sensor databases for semi-supervised learning by using auto-encoders to infer an efficient feature embedding [20].

ABSTRACT

“Sensor-free” detectors of student affect that use only student activity data and no physical or physiological sensors are cost-effective and have potential to be applied at large scale in real classrooms. These detectors are trained using student affect labels collected from human observers as they observe students learn within intelligent tutoring systems (ITSs) in real classrooms. Due to the inherent diversity of student activity and affect dynamics, observing the affective states of some students at certain times is likely to be more informative to the affect detectors than observing others. Therefore, a carefully-crafted observation schedule may lead to more meaningful observations and improved affect detectors. In this paper, we investigate whether active (machine) learning methods, a family of methods that adaptively select the next most informative observation, can improve the efficiency of the affect label collection process. We study several existing active learning methods and also propose a new method that is ideally suited for the problem setting in affect detection. We conduct a series of experiments using a real-world student affect dataset collected in real classrooms deploying the ASSISTments ITS. Results show that some active learning methods can lead to high-quality affect detectors using only a small number of highly informative observations. We also discuss how to deploy active learning methods in real classrooms to improve the affect label collection process and thus sensor-free affect detectors.

Keywords

Active learning, L-MMSE estimation, student affect detection

1. INTRODUCTION

Intelligent tutoring systems (ITSs) have gradually seen more and more deployment over the years in real classrooms all over the world. Recently, large-scale randomized controlled trials have shown that they can lead to improved student learning outcomes [30] and affect [19]. However, even the

state-of-the-art ITSs cannot interact with students the way human instructors can. For example, in real classrooms, instructors can detect a student’s knowledge and affective states by observing their activity and behavior and then adjust their teaching strategy by changing the difficulty of practice questions or addressing negative affect [2, 23]. In particular, keeping students in positive affective states (e.g., engaged) is crucial since their affective states are found to be highly predictive of many metrics of academic performance and success, including test scores [28] and college enrollment [29]. Consequently, there exist many works on designing interventions [1, 10] to address negative affect. Examples of such interventions include selecting appropriate textual dialogues to help students engage [12], using an embodied agent to mirror and empathize with confused students [6], and providing motivational message to frustrated students [19].

1.1 Student Affect Detection

Many existing student affect detection methods employ physical and physiological sensors that make frequent observations of students when they are learning. Despite their effectiveness, these detectors are impractical for large-scale deployment in real classrooms due to cost and privacy constraints [16, 35]. On the other hand, there exists a family of “sensor-free” detectors, which uses only student activity data as they learn within ITSs to detect affect [4, 32, 37]. These detectors use machine learning-based classifiers to predict student affective states from a set of activity features [5]. These sensor-free detectors are more feasible for large-scale deployment than those sensor-dependent ones for two reasons. First, they are cost-effective since once constructed, they can operate in fully-automated fashion and can easily be integrated into ITSs and deployed at large scale. Second, they are more privacy-aware since activity data can be more effectively anonymized than data obtained from other sensors, e.g., video recordings of the students’ facial expressions.

Although sensor-free affect detectors are highly automated, the student affect state label collection process remains labor-intensive. The process for collecting these labels typically consists of human observers (including trained coders and/or the teacher) making observations of students in real classrooms and encode their affect into a collection of states. For example, in the Baker Rodrigo Ocumpaugh monitoring protocol (BROMP) for affect observation and coding, there are four affective states: boredom, confusion, engaged concentration, and frustration. The process typically proceeds in round-robin fashion, i.e., the human observer alternates

Heffernan and Andrew Lan "Active Learning for Student Affect Detection" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 208 - 217

among students and observe one student in each observation interval according to a pre-defined, ad hoc schedule.

However, this data collection process is insufficient since the typical round-robin schedule cannot make full use of the limited time human experts have to make observations. The reason is that, due to the inherent diversity in student activity and affect, the affect states of some students during some observation intervals are more informative to the classifiers than those in other cases; A non-adaptive, ad-hoc observation schedule leads to a lot of missed opportunities to observe these more informative cases. Therefore, it is desirable to develop methods that adaptively select the most informative students to observe in each observation interval and recommend them to human observers. These adaptive methods can potentially lead to the collection of higher-quality data for the affect detector to train on without requiring additional human effort, which will ultimately improve affect detection.

1.2 Active Learning

Active learning refers to a family of machine learning methods that adaptively select the next most “informative” observation to a classifier [34]. These methods are designed for applications where one has access to abundant unlabeled data but can only selectively label a small portion of it. In this setting, there is a need to select data instances whose labels, once obtained, result in the largest improvement in classification quality. There exist numerous active learning methods with different metrics of informativeness; these methods have been found to be effective at reducing the amount of labeled data needed when combining with many classifiers including logistic regression [38], support vector machines [15], and deep convolutional neural networks [33]. See Section 3.1 for a more formal introduction to active learning.

Existing active learning methods are not always successful in practice; in some settings, no active learning methods can outperform the simple baseline approach of randomly selecting data instances to label [38]. One such setting is the “cold-start” setting, when one does not yet have access to a sufficient amount of data to build a good classifier. In this setting, the estimate of informativeness can be highly inaccurate. In affect detection, since there are typically hundreds of features used to summarize student activity in ITSs [5], a classifier needs a significant number of labels to reach reasonable quality. Therefore, the effectiveness of existing active learning methods will be limited in the initial part of the student affect label collection process. Another such setting is when the data is highly noisy; in this case, it is hard to identify informative observations. In affective detection, the affective state labels provided by human observers are highly subjective and thus noisy; the labels provided by different human experts may differ [27] significantly. Therefore, the effectiveness of existing active learning methods in affect detection will be limited by the noisiness of the data. Therefore, it is desirable to develop new active learning methods that are robust to small and noisy data.

1.3 Contributions

In this paper, we investigate whether active learning can be used to improve the efficiency and effectiveness of student

affective state label collection. We conduct a preliminary study using several classic active learning methods on an existing real-world student affect dataset collected from ASSISTments¹, a widely-used ITS. Motivated by the limitations of existing active learning methods when the data is small and noisy, we also propose a new active learning method that can excel in this setting. Our new active learning method leverages the recently proposed linear minimum mean squared error (L-MMSE) estimation framework [21, 22] to evaluate observation informativeness. This framework provides an exact, closed-form, and nonasymptotic analysis of the parameter estimation error for binary regression and is shown to be highly effective when data is small and/or noisy. Experimental results show that some active learning methods, especially our L-MMSE-based method, can reduce the number of labels needed to build high-quality, sensor-free affect detectors. We also discuss how to use active learning to improve data collection efficiency in real-world affect detection and possibly other quantitative field observation (QFO) tasks by building an interactive system that suggests human observers to make certain observations.

We emphasize that the purpose of the current work is *not* to improve affect detectors but rather to investigate whether one can collect better data to train them. Therefore, we resort to a simple logistic regression-based affect detector since it can be integrated with all existing active learning methods. More complicated, state-of-the-art deep learning-based detectors cannot be integrated with many active learning methods and thus do not offer us a complete view of active learning in affect detection.

2. RELATED WORK

ASSISTments is a free web-based platform that provides immediate feedback, on-demand hints, and scaffolding support to the many students who use it in classrooms and for daily homework [14]. The system has been used by hundreds of thousands of students and thousands of teachers, and has been found to be effective in improving learning outcomes and closing achievement gaps in a large-scale randomized controlled trial [30].

A significant amount of research has been conducted on the detection of student affect by aligning ASSISTments data to student affect labels collected in real classrooms using BROMP [27]. BROMP allows human observers to label a student in four often-studied affective states: engaged concentration [9], frustration [20], boredom [25], and confusion [8]. Initially, sensor-free affect detectors in ASSISTments leveraged a number of rule-based and statistics-based models; these models achieved performance substantially above chance, for new students from rural, suburban, and urban populations [4]. Later, the work in [36] improved upon these initial affect detectors by incorporating additional features on skills/knowledge components as well as statistics across the entire class. Most recently, the work in [5] applied deep learning methods to affect detection and produced a significant increase in detection accuracy. The key in that work is to use recurrent neural networks (RNNs), including its two popular variants in long short-term memory (LSTM) networks and gated recurrent unit (GRU) networks [13], to

¹<https://www.assistments.org/>

capture students' changing affect over time.

3. ACTIVE LEARNING

In this section, we will first review active learning and briefly describe how it can be used to improve the efficiency in QFOs. We will then review the L-MMSE estimation framework and introduce our new, L-MMSE-based active learning method.

3.1 Background on Active Learning

Supervised learning refers to a class of machine learning approaches where the task is to learn a function (usually, a classifier) that captures the relation between input-output (feature-label) pairs. The typical setup in supervised learning is that one observes all features and labels and can use them to train the classifier. Active learning, on the other hand, deals with the setting where one has control of the data label observation process; in this case, one has access to the feature values of all feature-label pairs but can select which one gets labeled next. Naturally, the most effective strategy is to train the classifier on observed labels and select the next label that is the most "informative" to the current classifier to observe [34]. There exist numerous active learning methods with different metrics of informativeness, e.g., entropy (or observation uncertainty) [24], expected error reduction [31], expected variance reduction [40], model change [7], etc. The goal of active learning is to only observe labels that are highly informative in order to learn the function more efficiently.

Concretely, we denote the functional relation between the features and labels as

$$\mathbf{y} \sim f_{\mathbf{x}}(\mathbf{D}),$$

where $\mathbf{y} \in \mathcal{A}^N$ is the vector of labels that contains a total of N observations. \mathcal{A} denotes the set of labels. $\mathbf{D} \in \mathbb{R}^{N \times P}$ denotes the matrix containing all feature values corresponding to each label. The column vectors corresponding to the rows of \mathbf{D} , i.e., the feature values of each observation, are denoted as \mathbf{d}_i , $i \in \{1, \dots, N\}$. Correspondingly, each element in the label vector is denoted as y_i , $i \in \{1, \dots, N\}$. $f_{\mathbf{x}}(\cdot)$ denotes the function that maps each input feature vector \mathbf{d}_i to each label y_i ; \mathbf{x} denotes the vector containing all parameters of the function. In regression problems, \mathbf{x} corresponds to the regression coefficient vector, while in neural networks, \mathbf{x} corresponds to the collection of all weights and biases that characterize the connections between hidden units.

The iterative process of active learning proceeds as follows. Suppose that one now has a set of $t-1$ observations, with $t \in \{1, 2, \dots, N\}$ and wants to select the next, t -th observation. Let \mathcal{O}_{t-1} and \mathcal{U}_{t-1} denote the *sets* (which contain indices) of all feature-label pairs (referred to as datasets) where the labels are observed and unobserved, respectively, and let $\hat{\mathbf{x}}_{t-1}$ denote the current estimate of the function parameters (trained on the subset of feature values and labels $\mathbf{D}_{\mathcal{O}_{t-1}}$ and $\mathbf{y}_{\mathcal{O}_{t-1}}$). Active learning methods then select the next observation i_t as

$$i_t = \operatorname{argmax}_{i \in \mathcal{U}_{t-1}} I(\mathbf{d}_i, \hat{\mathbf{x}}_{t-1}),$$

where $I(\cdot, \cdot)$ denotes a metric of how informative an observation i is to the current function. As an example, the simplest yet often most effective existing active learning method, uncertainty sampling, simply uses the entropy [13] as the metric

of informativeness:

$$I(\mathbf{d}_i, \hat{\mathbf{x}}_{t-1}) = - \sum_{a \in \mathcal{A}} p(y_i = a) \log p(y_i = a),$$

where $p(y_i = a) = f_{\hat{\mathbf{x}}_{t-1}}(\mathbf{d}_i)$ denotes the probability of a new observation with feature values \mathbf{d}_i taking on label a given the current function estimate parameterized by $\hat{\mathbf{x}}_{t-1}$. In other words, uncertainty sampling simply selects the next observation whose label the current classifier is the least certain of. After selecting the next observation, the classifier is re-trained using an updated observed dataset $\mathcal{O}_t = \mathcal{O}_{t-1} \cup \{i_t\}$. Then, in the next iteration of the active learning process, the next observation i_{t+1} is selected from an updated unobserved dataset \mathcal{U}_t .

In typical active learning settings, since one has access to all feature values, the unobserved dataset is simply updated by excluding the selected observation as $\mathcal{U}_t = \mathcal{U}_{t-1} \setminus i_t$. However, we emphasize that under real-world QFO settings, the set of unobserved observations can change entirely. For example, in the typical BROMP coding process, a human coder observes the affective state of one student in each observation interval (typically 20 seconds); therefore, in the next iteration, the set of unobserved dataset (which contains feature values that summarize student activity during the next observation interval) might change entirely.

3.2 Background on L-MMSE Estimation

The L-MMSE estimation framework put forward in [21, 22] enables the design of new estimators for a wide range of nonlinear classification and regression problems. It also offers a closed-form, exact, and nonasymptotic analysis of the estimation error for nonlinear problems, which is typically impossible to obtain. The key insight to the L-MMSE estimation framework is that even for nonlinear problems, well-crafted linear estimators that take the nonlinearity into account can achieve comparable performance to nonlinear estimators that are computationally extensive and hard to analyze. Therefore, it is an advanced estimation technique and shall not be confused with basic linear estimation methods like least squares.

In [22], the L-MMSE estimation framework is applied to binary (especially probit) regression, which is given by

$$\mathbf{y} = \operatorname{sign}(\mathbf{D}\mathbf{x} + \mathbf{w}),$$

where $y_i \in \{-1, +1\}$ denotes the binary-valued label for feature-value pair i . The vector $\mathbf{w} \in \mathbb{R}^N$ denotes a noise vector with i.i.d. standard normal random entries. Putting a zero-mean multivariate normal prior with covariance matrix $\mathbf{C}_{\mathbf{x}}$ on \mathbf{x} as $\mathbf{x} \sim \mathcal{N}(\mathbf{0}, \mathbf{C}_{\mathbf{x}})$, the L-MMSE estimator finds the best estimator of \mathbf{x} that is *linear* in the observation vector \mathbf{y} , i.e.,

$$\hat{\mathbf{x}} = \mathbf{W}\mathbf{y},$$

where \mathbf{W} is a suitably-chosen estimation matrix that achieves the minimum mean-squared error (MSE) defined as

$$\text{MSE} = \mathbb{E}_{\mathbf{x}, \mathbf{w}} [\|\mathbf{x} - \hat{\mathbf{x}}\|_2^2].$$

For probit regression, a variant of binary regression, the L-MMSE estimator has a closed-form expression, given by $\mathbf{W} = \mathbf{E}^T \mathbf{C}_{\mathbf{y}}^{-1}$, with its corresponding MSE given by

$$\text{MSE} = \text{tr}(\mathbf{C}_x - \mathbf{E}^T \mathbf{C}_y^{-1} \mathbf{E}), \quad (1)$$

where

$$\begin{aligned} \mathbf{E} &= \left(\frac{2}{\pi}\right)^{1/2} \text{diag}(\text{diag}(\mathbf{C}_z)^{-1/2}) \mathbf{D} \mathbf{C}_x, \\ \mathbf{C}_y &= \frac{2}{\pi} \sin^{-1} \left(\text{diag}(\text{diag}(\mathbf{C}_z)^{-1/2}) \mathbf{C}_z \right. \\ &\quad \left. \times \text{diag}(\text{diag}(\mathbf{C}_z)^{-1/2}) \right), \\ \mathbf{C}_z &= \mathbf{D} \mathbf{C}_x \mathbf{D}^T + \mathbf{I}. \end{aligned}$$

We note that the MSE (and also the matrix \mathbf{W}) depends only on the matrix \mathbf{D} and not the label vector \mathbf{y} .

3.3 L-MMSE-based Active Learning

Results in [21, 22] have shown that the L-MMSE estimator for binary regression performs on-par with state-of-the-art, sophisticated estimators, e.g., those that require using tools in convex optimization and Markov chain Monte Carlo techniques, while having much lower computational complexity. More importantly, the L-MMSE-based estimation error analysis is shown to be more accurate than other analyses (e.g., those that rely on Fisher information) when the data is noisy and/or when the data is small, i.e., when N is not much larger than P . This advantage is highly desirable in active learning settings and especially in affect detection for two reasons. First, in active learning settings, one often work with small problem sizes: in the initial stages of the active learning process, the classifier is highly inaccurate since it is only trained on a small number of observed labels; therefore, it can lead to an unreliable metric of informativeness which is the key to active learning methods. Second, in affect detection and a lot of other educational applications, the data is inherently noisy: state-of-the-art affect detectors can only achieve area under the receiver operating characteristic curve (AUC) values of around 0.7 after many empirical tweaks [5]. This accuracy is significantly lower than that in common classification tasks [13]. Moreover, inter-coder disagreement on a student's affective state can be high in some cases [27]; this disagreement is also reported in facial expression recognition-based affect detectors [3].

Therefore, we propose a new active learning method that uses the closed-form expression of the MSE of the L-MMSE estimator given in Eq. 1 to measure informativeness since it is reliable even for small and noisy data. Note that we do not use the L-MMSE estimator to estimate \mathbf{x} , but only its MSE to select the next observation. Specifically, we use the negative MSE as our metric of informativeness as

$$I(\mathbf{d}_i, \hat{\mathbf{x}}_{t-1}) = -\text{MSE}(\mathbf{D}_{\mathcal{O}_{t-1} \cup \{i\}}).$$

In other words, we select the t -th observation as the one corresponding to the feature vector \mathbf{d}_i that *minimizes* the resulting MSE, i.e.,

$$i_t = \underset{i \in \mathcal{U}_{t-1}}{\text{argmin}} \text{MSE}(\mathbf{D}_{\mathcal{O}_{t-1} \cup \{i\}}),$$

where $\mathbf{D}_{\mathcal{O}_{t-1} \cup \{i\}} = [\mathbf{D}_{\mathcal{O}_{t-1}}^T, \mathbf{d}_i^T]^T$.

Since the MSE is independent on the observations \mathbf{y} , the L-MMSE-based active learning method is likely more robust than all existing methods that rely on \mathbf{y} , especially during the initial stage of the active learning process when the number of observations is small. Therefore, it is likely to be highly

effective in real-world QFO and especially affect detection settings. This intuition is confirmed by our experiments in Section 4.

In practice, the MSE can be computed very efficiently since the inverse of the matrix \mathbf{C}_y^{-1} only needs to be computed once in every iteration; we do not need to invert it for every potential observation added to the current set of observations. For simplicity of exposition, we temporarily drop the subscripts and use \mathbf{D} and \mathbf{d} to denote the current feature matrix and the feature vector for a possible new observation. The new matrix \mathbf{C}'_z is given by

$$\mathbf{C}'_z = \begin{bmatrix} \mathbf{D} \\ \mathbf{d}^T \end{bmatrix} \mathbf{C}_x [\mathbf{D}^T \ \mathbf{d}] = \begin{bmatrix} \mathbf{C}_z & \mathbf{D} \mathbf{C}_x \mathbf{d} \\ \mathbf{d}^T \mathbf{C}_x \mathbf{D}^T & \mathbf{d}^T \mathbf{C}_x \mathbf{d} + 1 \end{bmatrix}.$$

Now, the new matrix \mathbf{C}'_y is given by

$$\begin{aligned} \mathbf{C}'_y &= \frac{2}{\pi} \sin^{-1} \left(\text{diag}(\text{diag}(\mathbf{C}'_z)^{-1/2}) \mathbf{C}'_z \text{diag}(\text{diag}(\mathbf{C}'_z)^{-1/2}) \right) \\ &= \frac{2}{\pi} \sin^{-1} \left(\begin{bmatrix} \text{diag}(\text{diag}(\mathbf{C}_z)^{-1/2}) & \mathbf{0} \\ \mathbf{0}^T & (\mathbf{d}^T \mathbf{C}_x \mathbf{d} + 1)^{-1/2} \end{bmatrix} \right. \\ &\quad \cdot \begin{bmatrix} \mathbf{C}_z & \mathbf{D} \mathbf{C}_x \mathbf{d} \\ \mathbf{d}^T \mathbf{C}_x \mathbf{D}^T & \mathbf{d}^T \mathbf{C}_x \mathbf{d} + 1 \end{bmatrix} \\ &\quad \cdot \left. \begin{bmatrix} \text{diag}(\text{diag}(\mathbf{C}_z)^{-1/2}) & \mathbf{0} \\ \mathbf{0}^T & (\mathbf{d}^T \mathbf{C}_x \mathbf{d} + 1)^{-1/2} \end{bmatrix} \right) \\ &= \begin{bmatrix} \mathbf{C}_y & \mathbf{c} \\ \mathbf{c}^T & 1 \end{bmatrix}, \end{aligned}$$

where $\mathbf{c} = \frac{2}{\pi} \sin^{-1} \left((\text{diag}(\mathbf{C}'_z)^{-1/2}) \mathbf{D} \mathbf{C}_x \mathbf{d} (\mathbf{d}^T \mathbf{C}_x \mathbf{d} + 1)^{-1/2} \right)$. Now, using the block matrix inversion rule [17], we have

$$\mathbf{C}'_y{}^{-1} = \begin{bmatrix} \mathbf{C}_y^{-1} + h \mathbf{g}^T \mathbf{C}_y \mathbf{g} & h \mathbf{g} \\ h \mathbf{g}^T & h \end{bmatrix},$$

where $\mathbf{g} = -\mathbf{C}_y^{-1} \mathbf{c}$ and $h = \frac{1}{1 - \mathbf{c}^T \mathbf{C}_y^{-1} \mathbf{c}}$. Now, the new matrix \mathbf{E}' is given by

$$\begin{aligned} \mathbf{E}' &= \left(\frac{2}{\pi}\right)^{1/2} \begin{bmatrix} \text{diag}(\text{diag}(\mathbf{C}_z)^{-1/2}) & \mathbf{0} \\ \mathbf{0}^T & (\mathbf{d}^T \mathbf{C}_x \mathbf{d} + 1)^{-1/2} \end{bmatrix} \\ &\quad \cdot \begin{bmatrix} \mathbf{D} \\ \mathbf{d}^T \end{bmatrix} \mathbf{C}_x = \begin{bmatrix} \mathbf{E} \\ \mathbf{e}^T \end{bmatrix}, \end{aligned}$$

where $\mathbf{e} = \left(\frac{2}{\pi}\right)^{1/2} (\mathbf{d}^T \mathbf{C}_x \mathbf{d} + 1)^{-1/2} \mathbf{D} \mathbf{C}_x \mathbf{d}$. Therefore, plugging all of the above into Eq. 1 and some algebra, we get an expression for the new MSE after adding a new observation with feature value vector \mathbf{d}_i as

$$\begin{aligned} \text{MSE}' &= \text{tr}(\mathbf{C}_x) - \text{tr}(\mathbf{E}'^T \mathbf{C}'_y{}^{-1} \mathbf{E}') = \text{tr}(\mathbf{C}_x) \\ &\quad - \text{tr} \left(\begin{bmatrix} \mathbf{E}^T & \mathbf{e} \end{bmatrix} \begin{bmatrix} \mathbf{C}_y + h \mathbf{g}^T \mathbf{C}_y^{-1} \mathbf{g} & h \mathbf{g} \\ h \mathbf{g}^T & h \end{bmatrix} \begin{bmatrix} \mathbf{E} \\ \mathbf{e}^T \end{bmatrix} \right) \\ &= \text{tr}(\mathbf{C}_x) - \text{tr}(\mathbf{E}^T \mathbf{C}_y^{-1} \mathbf{E}) - h \text{tr}(\mathbf{E}^T \mathbf{g}^T \mathbf{C}_y^{-1} \mathbf{g} \mathbf{E}) \\ &\quad - 2h \text{tr}(\mathbf{E}^T \mathbf{g} \mathbf{e}^T) - h \text{tr}(\mathbf{e} \mathbf{e}^T) \\ &= \text{MSE} - h(\|\mathbf{E}^T \mathbf{g} + \mathbf{e}\|_2^2), \end{aligned} \quad (2)$$

where the reduction in MSE induced by making a new observation is given by the term $h(\|\mathbf{E}^T \mathbf{g} + \mathbf{e}\|_2^2)$. Therefore, we can obtain the new MSE without having to explicitly calculate $\mathbf{C}'_y{}^{-1}$ for every possible new observation. In our experiments, we found that this implementation speeds up the L-MMSE-based active learning method by 10 to 100 times, resulting in an empirical computational complexity

that is lower than most existing active learning methods except uncertainty sampling.

4. EXPERIMENTAL RESULTS

We now perform a series of experiments on a real-world student affect dataset to explore the effectiveness of active learning methods. We start by adopting standard experimental protocols for active learning under several different settings and then present a simple example to help us understand the conditions under which active learning methods are the most effective.

4.1 Student Affect Dataset

We use an existing dataset for building sensor-free affect detectors collected in real classrooms² [5]. The dataset consists of 3,109 observations, each observation contains i) a student's affective state label during a 20-second observation interval in real classrooms and ii) a set of 88 features that summarizes their activities within ASSISTments during this time interval. These features include the time each student spent on practice items, the number of hints they seek, and the correctness of their responses. We keep observations where the student is labeled as being in one of the four affect states under BROMP: bored, confused, engaged concentration, and frustrated. We leave out the few observations where the human coder indicates that either the student is not in any of the four states or that they are not sure what state the student is in. Engaged concentration is the most frequent state among the four, which occurs about 82% of the time.

Since we focus on logistic regression-based affect detectors in this paper, we need to construct a binary classification problem by detecting the presence of one of the four affective states. We start by building a detector of the engaged concentration affective state since it is the most common among the four states.

4.2 Baseline Active Learning Methods

We test four different active learning methods in our experiments: i) our L-MMSE-based active learning method, (ii) uncertainty sampling (US) [24], as introduced in Section 3.1, (iii) expected variance reduction (EVR) [40], which selects the next observation as the one that results in the largest reduction of the variance of the classifier, and (iv) model change (MC) [7], which selects the observation that changes the classifier's parameters the most. We also use random sampling (Random), which randomly selects the next observation, as the baseline method to simulate the round-robin observation schedule followed in real classrooms when the dataset was collected. We do not test another popular active learning method, expected error reduction [31], since it has very high computational complexity and does not outperform other methods in several preliminary experiments.

4.3 Engaged Concentration Detection

We start by testing active learning methods for a detector of engaged concentration vs. other affective states.

4.3.1 Experimental setup

²This dataset is taken from <http://tiny.cc/affectdata>

We use cross validation to test the performance of active learning methods on the ASSISTments student affect dataset. We use two different settings for cross validation: we split the dataset at both the observation level (where each observation is regarded as a stand alone instance) and the student level (where all observation on a student is considered as an instance). We randomly select 20% and 10% of all instances as the test and validation sets, respectively, and use the rest as the training set. The test set is used to evaluate the predictive quality of the trained classifier, using the area under the receiver operating characteristic curve (AUC) metric [18]. This metric takes value in $[0, 1]$ and larger values indicate higher predictive quality.

We start by randomly selecting an initial batch of $M \in \{20, 100, 500\}$ observations (with both student activity feature vector and affective state label for each observation) from the training set; we then use them to train a base logistic regression classifier and use it as our initial affect detector. This experimental setting enables us to study the effectiveness of active learning methods when the amount of prior data available to the detector varies. Although the L-MMSE-based analysis is based on probit regression, we use the more widely-adapted logistic regression to test its robustness against model mismatch. The base classifier is trained using accelerated gradient descent [26] implemented in TensorFlow³ with a $P \times 1$ zero-vector as the initializer. We do not regularize the logistic regression classifier and instead use the validation set to decide when to terminate the training process and avoid overfitting. Specifically, after each (accelerated) gradient descent step, we evaluate the current detector on the validation set, and stop once its predictive quality stops improving (as measured by AUC).

Then, in each iteration of the active learning process, we select the next observation from the remaining ones in the training set according to their feature values, for each active learning method. We then add this new observation (both its feature vector and label) to the current batch and re-train the affect detector, using the previous estimate of the regression coefficients as the initializer. We then calculate the AUC of the re-trained affect detector on the test set. We repeat these steps for a total of 50 additional observations; using more data points is unnecessary since i) we found that using 50 additional observations is enough to summarize the behavior of each active learning method and ii) the performance of the affect detector will converge to the same end point for each active learning method, after going through the entire training set. We also repeat our experiment 100 times and use a different random split of the full dataset and a different initial batch of observations each time. We then report the average results over these repetitions.

4.3.2 Results and discussion

Figure 1 plots the AUC values of the trained affect detectors on the held-out test set vs. the number of additional observations, for all active learning methods on the student affect dataset, using observation-level cross validation. We see that most active learning methods, except EVR, generally outperforms random observation selection when the quality of the affect detector is limited by the amount of data it

³<https://www.tensorflow.org/>

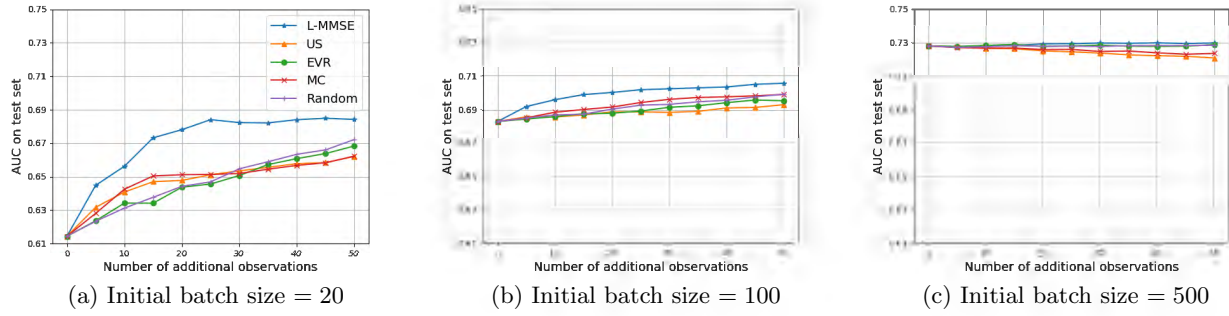

Figure 1: Comparison between different active learning methods for engaged concentration detection with observation-level cross validation. Most active learning methods, especially our L-MMSE-based active learning method, are effective at small initial batch sizes. This advantage over random observation selection diminishes as the quality of the detector saturates when a large number of observations is made.

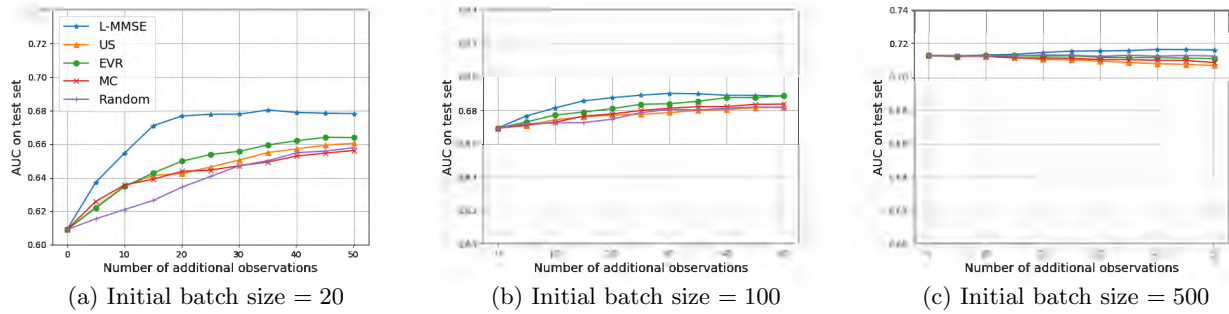

Figure 2: Comparison between different active learning methods for engaged concentration detection with student-level cross validation. The behavior of active learning methods remain largely the same as observation-level cross validation: they are most effective when the affect detector is trained on few observations.

sees (when it is trained on no more than 50 observations). Our L-MMSE-based method significantly outperforms every other method in this setting. As a concrete example, with 25 additional observations added to the 20 observations in the initial batch, the L-MMSE active learning method results in an AUC of 0.685 on the test set, while no other method result in a detector that has an AUC above 0.65. This result suggests that the L-MMSE-based active learning method excels at picking out observations that are crucial to the affect detector immediately, despite the detector’s limited predictive quality; its performance in this setting is impressive since the number of features is quite large ($P = 88$), which is even more than the number of observations in Figure 1(a). Moreover, to reach an AUC value of 0.685 on the test set, the L-MMSE-based active learning method only needs 45 total observations; no other active learning method can achieve this predictive quality even with 70 total observations. This result suggests that, by directing human experts at making observations that are more meaningful to the affect detector, active learning methods can potentially improve the quality of the data without requiring more human effort.

We demonstrate the statistical significance of our results using Student’s t-test. Table 1 shows the p-values for rejecting the null hypothesis that the best performing active learning method (L-MMSE) over random observation selection, with

No. of observations	20	30	40	70	100
p-value	3×10^{-3}	2×10^{-7}	2×10^{-9}	6×10^{-3}	4×10^{-1}

Table 1: Statistical significance of the advantage active learning (the L-MMSE-based method) exhibits over random observation selection. Active learning methods are significantly better at the initial stage of the affect observation process.

an initial batch size of $M = 20$. We see that initially, when the affect detector is not highly accurate, active learning has a significant advantage over random observation selection.

As the size of the initial batch increases ($M = 100$) and the quality of the initial affect detector improves, the advantage of the L-MMSE-based active learning method over random observation selection drops and eventually diminishes when $M = 500$. This result is not surprising since with 500 initial observations, the performance of the affect detector already saturates (the AUC on the test set after training on the entire training set is 0.74, which is consistent with the values reported in [5]). However, even in this case, the L-MMSE-based active learning method still provides some improvement compared to random observation selection (about 0.01 AUC on the test set with 100 to 150 observations in Figure 1(b)). We note that this advantage is not statistically significant

(see Table 1), which is not surprising since the quality of the affect detector improves very slowly after the first 50 observations, leaving very little room for active learning to show its effectiveness.

Perhaps surprisingly, no active learning method except our L-MMSE-based method consistently outperforms random observation selection, even when the initial batch size is small. When the initial batch size is large ($M = 500$), US and MC even leads to worse affect detectors, although we suspect that the performance degradation in that case is due to randomness in cross validation not being sufficiently smoothed out rather than a poor affect detector. These results confirm our intuition that active learning methods designed for general-purpose classification tasks are not well-suited to affect detection, especially when the data size is small during the initial stage of the data collection process.

Figure 2 plots the AUC values of the trained affect detectors on the held-out test set vs. the number of additional observations for all active learning methods, using student-level cross validation. The results largely remain the same compared to observation-level cross validation. Overall, there is a small drop of about 0.01 in test set AUC, confirming the intuition that it is harder for affect detectors to generalize to unseen students than to generalize to unseen observations from current students. However, the L-MMSE-based active learning method still (perhaps even more) consistently outperforms other active learning methods and random observation selection. As a concrete example, with only 10 additional observations in addition to an initial batch of 20 observations, the L-MMSE-based active learning method achieves an AUC of 0.655 on the test set; the other active learning methods and random observation selection achieve AUC values 0.635 and 0.62, respectively. In this case, the effectiveness of using active learning methods (especially our L-MMSE-based method) to identify informative observations and use them to improve affect detection is obvious.

Our experimental results also suggest that there is a lot of redundancy in the ASSISTments student affect dataset. As we discussed above, the quality of the affect detectors saturates after training on about 500 observations. Consider that the entire training set contains more than 2,100 observations, it seems that the majority of them do not significantly contribute to the quality of the resulting affect detector. This discovery further emphasizes the need of using smarter ways to collect higher-quality data; see Section 5 on a detailed discussion of how to use active learning methods to possibly improve data quality in practice.

4.4 Detection of Other Affective States

We now test the effectiveness of active learning methods for the detection of the other three affective states in BROMP: bored, confused, and frustrated.

4.4.1 Experimental setup

Since these affective states are rare (bored occurs about 10% of the time, while confused and frustrated each occur about 4% of the time) in the ASSISTments dataset, prior work [5, 28] uses resampling to balance among the affective states. Specifically, these works build training datasets that contain roughly equal numbers of observations corresponding

to each affective state by resampling from the original training set; after affect detectors are trained on the resampled training dataset, they are then evaluated on the original, non-resampled test set.

We do not use the resampling technique since our goal is to simulate the actual affect observation setting in real-world classrooms, where the four affective states are naturally unbalanced. Therefore, we use same experimental setting as before, except that we have to resort to larger initial batch sizes to ensure that at least a few rare affective states occur in the initial batch. In our experiments, we found that using an initial batch size of $M = 100$ is sufficient.

4.4.2 Results and discussion

Figure 3 plots the AUC values of the trained detectors on the held-out test set vs. the number of additional observations, for the affective states of bored, confused, and frustrated. We used different y-axis ranges in each of the three subplots to enhance contrast since for the confused and frustrated states, the improvement in the quality of the detectors as more observations are made is small. We see that active learning methods, especially our L-MMSE-based method, can still generally outperform random observation selection in most cases (especially for the bored state). However, this advantage is much smaller for these infrequent affective states compared to engaged concentration. For the detection of confusion, two of the active learning methods (US and MC) consistently underperform random observation selection, while our L-MMSE-based method shows some improvement only initially. The only active learning method that performs on-par with random observation selection is the EVR method. One possible explanation is that for harder-to-detect affective states like the confused state, the quality of the classifier is quite low (the final AUC on the test set is only 0.67), which leaves little room for active learning to show its effectiveness.

We now present a simple example to give us some insights on the conditions under which active learning methods are most effective in affect detection. Figure 4 compares the portion of observations selected by an active learning method (US) that actually correspond to an infrequent affect (we used the bored state as an example) to that of random observation selection. We see that after using the initial batch of observations to build a (low-quality) detector, active learning methods can quickly use it to select the observations that actually correspond to the infrequent target affect. Specifically, within the first 50 additional observations, US selects about 15 observations that correspond to the bored affective state, using only student activity features, as it deems these observations more informative; this portion (about 30%) is much higher than the overall portion of the bored state in the entire training set (about 10%). This behavior of US is consistent across all affective states except the confused state, where the portion of observations it selects that actually correspond to the confused state does not exceed the overall portion. In that case, active learning methods also fail to consistently outperform random observation selection, as shown in Figure 3(b). Therefore, active learning methods seem to be effective only if they can strike the right balance between observing different affective states that occur at different frequencies.

Figure 3: Comparison between different active learning methods for infrequent affective state detection (bored, confused, and frustrated). Active learning methods are generally effective for the bored and frustrated states but not the confused state. Their advantage over random observation selection for these states is smaller than that for engaged concentration detection.

Figure 4: Portion of total infrequent affective state observations selected by an active learning method (US) versus random observation selection for boredom detection. Active learning methods can effectively select observations that actually correspond to the infrequent affect.

5. DEPLOYMENT IN CLASSROOMS

We now outline how to deploy active learning methods in real classrooms to improve the data collection efficiency for affect detection. Since active learning requires training affect detectors on-the-fly as new observations are made, there is a need to create a system that consists of three components. The first component is an interface to human observers making observations in classrooms; this interface i) suggests the human observer to observe a student at each observation interval, ii) collects their affect label on the student, and iii) send the label to the affect detector. The second component is a training paradigm for affect detectors that keeps updating the detector by re-training it after it receives each observed affect label and its corresponding feature vector. The third component is the active learning method that links the other two components together: it i) uses APIs to collect student activity data from ITSs and turn them into feature vectors, ii) selects the next observation that is the most informative to the current affect detector and sends its suggestion via the human observer interface.

There are several realistic considerations in such a system in order for it to be deployed in real classrooms. First, our

experiments (see Section 4.4) have shown that active learning methods are not as effective for affective states that occur infrequently (especially the confused state). Therefore, there is a need to explore more advanced active learning methods that take class imbalance into account [11]. Second, experienced human observers may have their own understanding of the informativeness of an observation; such understanding can also be highly valuable to machine learning-based affect detectors. Therefore, the human observer interface should present an option that allows them to ignore the suggestion by active learning methods and instead propose which students to observe on their own. Third, fairness among different student subgroups [39] is critical; we want to ensure that each subgroup is well-observed in the data collection process. Therefore, there needs to be an exploration mechanism that checks whether a student subgroup is under-observed and limit active learning methods to only select among those students when that happens.

6. LIMITATIONS AND FUTURE WORK

In this paper, we have explored the problem of whether active learning methods can be used to increase the efficiency of the affective state label collection process for the development of sensor-free affect detectors. Using an existing student affect dataset collected from ASSISTments, we have shown that active learning methods are indeed effective at making observations that are the most informative to the affect detector; therefore, it can reduce the number of observation needed for the detector to reach a certain quality under most settings. We also proposed a new active learning method that is especially effective for small and noisy data; experimental results show that it outperforms existing active learning methods. At the end, we outlined how to deploy these methods in real-world systems to improve the quality of the data to be collected and discussed several necessary considerations under practical constraints.

Despite the effectiveness of active learning methods, especially our L-MMSE-based method, our work has several limitations and can be extended in many different ways. First, our experimental setting for active learning does not perfectly reflect the actual affective state observation process in real classrooms. In our experimental setting, we select the next observation from all available observations left in the

training set, which was collected in many classroom sessions over a long period of time. In practice, when a human observer is making observations in real classrooms, we can only select an observation among the students in class; the most informative observation among these students is generally less informative than the most informative observation possible. Therefore, the benefit active learning methods bring to real-world affect label collection may not be as much as what we have shown in our experiments.

Second, the affect detectors we have studied in this paper are only for detecting the presence of a particular affective state, e.g., bored vs. not bored; it cannot jointly detect all possible affective states. The reason we did so is to test as many active learning methods as possible since most of them are designed only for binary classification. Unfortunately, the most effective active learning method for affect detection in our experiments (our L-MMSE-based method) only applies to binary classification tasks. Therefore, for real-world affect detection problems that are multi-class classification problems, we will extend our method so that it can be applied to multinomial logistic regression instead of binomial logistic regression.

Third, state-of-the-art affect detectors use neural networks rather than logistic regression as their base classifier [5]. While some active learning methods (e.g., uncertainty sampling) can be easily extended to neural networks, others (e.g., our L-MMSE-based method, variance reduction methods, and methods based on model change) cannot since they are either theoretically grounded in binary regression or become computationally intractable. Fortunately, the L-MMSE estimation framework encapsulates all the common nonlinearities used in today's state-of-the-art neural network architectures, including the hyperbolic tangent and rectified linear nonlinearities [13]. Therefore, we will extend the L-MMSE-based active learning method proposed in this paper to leverage neural networks as the base classifier.

Fourth, the workflow we outlined for the deployment of active learning in a real-world system in Section 5 presents a time mismatch challenge. In order to select an observation that the human observer should observe, we need access to the corresponding student activity feature vector; these feature values, however, are not available until the end of the observation time interval since many features summarize a student's activity during the entire period. When the teacher receives a suggestion to observe a certain student, this suggestion will be based on the student's activities during the last observation interval, which may not be the most informative observation during the current observation interval. Therefore, we will need to perform a thorough analysis of the coherence in student activity and affect over time to validate the feasibility of deploying active learning in real-world systems for affect label collection.

Finally, the essence of using active learning for affect detection is to leverage the judgement a machine learning-based detector makes on how sure it is about the affective state of a student. Simultaneously, human observers who are trained to make observations in classrooms have their own judgements on how sure they are about a student's affective state. Therefore, comparing the two sets of judgements may lead

to deeper insights on how humans perceive affect. Moreover, there is an intrinsic mismatch between the two sets of judgements since one is based on a set of activity features in ITSs while the other is based on observations of activity, gesture, and facial expressions. Therefore, comparing the two sets of judgements may also lead to an analysis of the extent to which the activity features can capture student affect; these insights can potentially help us to design better student activity features or even lead to better ITS designs.

ABSTRACT

Viewing worked examples before problem solving has been shown to improve learning efficiency in novice programming. Example-based feedback seeks to present smaller, adaptive worked example steps during problem solving. We present a method for automatically generating and selecting adaptive, example-based programming feedback using historical student data. Our data-driven feature-based (DDF) example generation method automatically learns program features from data and selects example pairs based on when students complete each feature. We performed an experiment to compare three example generation methods: Student trace data, Data-Driven Features (DDF), and Expert examples. Two experts rated the quality of feedback for each generator, and they rated both the Expert and DDF example feedback as significantly more relevant to students' goals than the Student example feedback. However, there were no significant differences between the DDF and Expert examples. We compared these approaches to one that combined DDF with an Interactive Selection step (DDF-IS), where the user (in this case, an expert) selects their preferred data-driven feature before an example is selected. DDF-IS produced significantly more relevant examples than all other approaches, with significantly higher overall example quality than DDF. This suggests that our DDF approach allows more relevant examples to be selected than existing approaches, and that we may be able to leverage interactivity with the student to further improve example quality.

1. INTRODUCTION & BACKGROUND

Prior studies show that worked examples are an effective instructional support to help novices learn complex tasks [27, 30, 28, 8]. Sweller argues that "...for novices, learning via worked examples should be superior to learning via problem solving." [27]. In the domain of programming, researchers

also suggest using worked examples to teach novices [3, 31]. Empirical studies have shown that interleaving worked examples with similar practice problems is more effective than solving only equivalent programming problems by writing code, as students spent less time on training tasks and performed better on a posttest [30]. However, worked examples are traditionally only offered to students in between problem solving attempts [30, 16, 7, 6], and they do little to assist students when they have difficulty *during* problem solving. Based on the idea of worked examples, researchers have explored example-based feedback [9, 4, 13], which shows a correct piece of code to help students learn during problem solving, as a form of adaptive, on-demand support [9]. Similar to a high-level on-demand hint, example-based feedback demonstrates one step in a correct solution to the problem the student is working on, selected adaptively to match the student's code. Keuning et al. argue for the need for such feedback in their review on automated feedback generation for programming, saying "the very low percentage of tools that give code examples based on the student's actions is unfortunate, because studying examples has proven to be an effective way of learning" [15]. As Gross et al. argue, showing a relevant partial solution could impose less cognitive load and be easier to visually present to novices than showing a full solution [9]. Ichinco et al. found that novices have trouble transferring what they learned from similar problems to their own code [14]. Example-based feedback addresses this by providing example steps from the *same* problem the student is working on. Figure 1 presents a prototype of what example-based feedback might look like in a block-based novice programming environment. The example is presented with a "before" state, similar to the student's current code, and an "after" state that completes a desired feature, helping the student easily identify the purpose and outcome of a single solution step.

Existing example-based feedback systems may rely on a library of expert-authored examples [11, 14, 4], which can be costly to maintain, as instructors are unlikely to create new examples [12]. Additionally, the example code may show an example solution to a related problem [11] that requires students to transfer knowledge to solve their current problem, which may be challenging for weaker students who need more help [13]. To address these limitations, we present a

Figure 1: Example-based feedback prototype in iSnap.

data-driven method to create example-based feedback using historical student data. We focus on the domain of programming, where many problems have a vast space of possible solutions [24, 19], so a static set of examples is unlikely to be relevant to all students. To our knowledge, only Gross et al. have previously employed a data-driven method to derive examples adaptively to help students [9]. They found that examples derived from expert solutions are perceived by students as more helpful and help students make more solution improvements than those derived from student solutions. However, they simply presented the complete student solution which was most similar to the current student’s code (according to a distance metric), rather than trying to systematically identify and address students’ current programming goals. This suggests that existing evaluations of data-driven methods for example-based feedback have not explored the full potential of the approach. We hypothesize that with the innovations in this work, data-driven examples can be more adaptive than expert-authored ones, while still presenting correct and interpretable solution steps.

In this work, we present an approach to automatically detect students’ progress towards a solution, and suggest example-based feedback from historical student data. Our data-driven method first processes prior correct student solutions to discover meaningful features, labels the parts of code that contribute to each feature, and removes code that does not contribute to the solution, to create simple data-driven code examples that contain only the code needed for each feature. We then automatically label the student’s current code with a “feature state” representing the presence or absence of each data-driven feature needed for a correct solution. We then adaptively select example feedback that contains the same features as the current student code, and adds a new feature that is relevant to solving the current problem. In contrast, other example feedback systems show code from a related similar problem, requiring students to study the example and transfer what they learn to the current context [11].

We evaluated two data-driven methods to generate and select example-based feedback for historical student hint requests: Data-Driven Features (DDF), and Data-Driven Features with Interactive Selection (DDF-IS). We compared these methods against two baselines: (1) Expert-authored examples (Expert) and (2) examples generated naively from correct student solution traces, showing the code added between consecutive test runs (Student). The data-driven features (DDF) algorithm cleans prior students solutions and generates example pairs where the “start code” has the same features as the student’s code, and the “end code” adds a new feature that is not yet present in the student’s code.

The DDF with Interactive Selection (DDF-IS) approach explored the potential to improve algorithmic DDF example feedback selection by having a user interactively select the data-driven feature with which they want help, before the algorithm selects an example. To simulate this experience, we used an expert to select this feature, representing a best-case scenario for interactive selection.

We adapted a multidimensional data-driven hint evaluation rubric from previous work to evaluate the example-based feedback quality based on Relevance, Progress, Interpretability, and Similarity. Our findings showed both the Expert and DDF feedback were significantly more relevant to students’ goals than the Student feedback, but there were no significant differences between the DDF and Expert examples. This suggests that our DDF feedback can reasonably replace Expert-authored examples in situations where they are unavailable or difficult to scale. We also found that DDF-IS produced significantly more relevant examples than all other approaches, with the highest overall example quality, significantly higher than DDF. This suggests that in the best case, data-driven feedback may leverage interactivity with the student to further improve example quality.

The contributions of this paper are: 1) a data-driven algorithm capable of generating adaptive example feedback for students during programming, and 2) an initial evaluation showing that these adaptive examples can be more relevant than static, expert-authored examples.

2. METHOD

This work presents and evaluates a data-driven feature-based (DDF) method for generating and selecting example-based feedback (explained in Section 2.2). To evaluate our DDF approach, we generated example-based feedback for historical student help requests, and asked experts to evaluate the quality of each type of feedback, comparing against two baselines (explained in Section 2.3.1).

2.1 Dataset

Our dataset comes from iSnap [20], which extends the Snap! block-based programming environment with logging and on-demand, data-driven hint support. It logs student interactions with the system, including complete code snapshots after each edit. The data were collected during the Fall 2016 (F16), Spring 2017 (S17), and Fall 2017 (F17) semesters in an introductory computing course for non-majors, held at a research university¹. In each semester, the students completed 3 in-lab assignments with access to help from teaching assistants and 3 homework assignments independently. In this paper, we selected one homework assignment *Squirrel* for the example code generation and evaluation. In *Squirrel* (shown in Figure 2), students program a “sprite” to draw a spiraling square-like shape using loops, variables, arithmetic operators and a custom block (function). Common solutions for *Squirrel* contain 7-10 lines of code. The original dataset contains 57 (F16), 43 (S17), and 47 (F17) *Squirrel* assignment submissions. Since iSnap offers students on-demand, data-driven hints which may alter students’ problem-solving patterns, we exclude students who requests hints in the dataset

¹All datasets are available at <https://pslcdatashop.web.cmu.edu/Project?id=321>

Figure 2: Squirrel pseudocode, Snap! code and output [34].

used for the example-based feedback generation. Our remaining data contained 38, 29, 39 code traces for the F16, S17, and F17 semesters, respectively. Each code trace contains the set of timestamped snapshots that comprise all of a student’s work on a problem.

2.2 Example-based Feedback Generation

We propose an algorithm to automatically generate data-driven, example-based feedback with the following high-level steps: 1) Extract a set of data-driven features from prior student code traces, which each describe a property of a correct solution. 2) Use the features to clean correct student code traces by removing extraneous code that does not contribute to a correct solution. 3) Generate pairs of example code snapshots that demonstrate how to complete a single feature. 4) Choose an appropriate, personalized example pair upon student request.

Our goal in this work is to perform a preliminary evaluation of our algorithm before implementing a user interface and evaluating its impact in practice. However, to contextualize our work, Figure 1 presents one way that such feedback could be presented to a student in iSnap when they request help. Our DDF example pairs consist of “start code,” similar to the student’s, and “end code” that demonstrates how to complete a single feature. Our design draws inspiration from a variety of theoretical and empirical sources, including cognitive load theory [29], Vygotsky’s Zone of Proximal Development [32], worked examples [27], learning from subgoals [16], and compare/contrast tasks [17].

Research on worked examples suggests that seeing examples which break a problem down into sequential steps (e.g. features) can be a more efficient way of learning than problem solving [27, 30, 28]. According to cognitive load theory, worked examples are effective because they lower the extraneous cognitive load (mental effort) imposed by the instructional materials. We designed our examples to present steps as a pair of “start” and “end” code, as previous studies have shown that comparing and contrasting examples is an effective learning activity in many domains [17, 26]. The example is adaptively selected to keep students in the Zone of Proximal Development [32] by starting with code similar to the student’s, which they can already understand, and scaffolding the completion of a new feature, which they cannot yet accomplish on their own. The work of Morrison et al. [16] suggests that programming examples that are broken into subgoals can help improve learning for novices. When examples are isomorphic to the problem solving task, as in our case, they found that it is most effective for students to label subgoals themselves, a feature we could easily incorporate into our example-based feedback.

2.2.1 Step 1: Data-driven Feature Generation

The goal of an example pair is to present how a meaningful self-contained portion of solution code, or *feature*, can be completed. An assignment may have students program multiple features, and the final correct solution should have all the correct features present. For example, in Squirrel (shown in Figure 2), a feature could be to move the sprite in a square shape, draw some figure on the screen, or repeat the spiral the correct number of times. In our previous work [34], we manually defined expert-authored features (shown in Table 1) in a systematic way, and we also implemented a data-driven algorithm to automatically identify code features from student solutions. Our results showed that many of the data-driven features were easily interpretable and closely matched the expert-authored features. The two methods also had moderate agreement on whether a given student was in the same state or different states.

The full procedure for data-driven feature extraction is given in [34], but we outline its high-level steps as follows:

- 1) **Preprocess student solutions:** Some student solutions may contain extraneous code or procedures that were used for testing or resetting the environment, which we attempt to remove before extracting features. Specifically, we used the SourceCheck algorithm [21] to identify and remove whole scripts and procedures that do not match any element of an expert-authored solution in the correct student solutions.
- 2) **Generate code shapes:** To identify common code patterns in correct student solutions, we extract a set of *code shapes*, or syntactic structures, from the solution code by converting students’ solution code into abstract syntax trees (ASTs) and then identify all pq-Gram subtrees [1] in each AST, to form our initial set of “code shapes.” This includes all code shapes from all correct solutions.
- 3) **Remove duplicates:** The initial set of code shapes may include very similar shapes, including some AST patterns that are subsets of others. Therefore, we remove these duplicates by measuring the co-occurrence of code shapes in all student code traces and keeping only the more specific code shape and discard the other duplicate if two code shapes almost always appear together in the same code.
- 4) **Identify decision shapes:** Due to varied problem solving strategies, some code shapes may not appear in every correct solution. For example, a Squirrel solution can either use nested repeat or a single repeat block to rotate the correct number of times (as shown in Figure 2), but not both. Therefore, we define a *decision shape* as a disjunction of code shapes, where almost all solutions contain exactly one of the component code shapes. A decision shape is present in a solution if any one of its code shapes exist in its code.
- 5) **Filter out uncommon code and decision shapes:** Since we are interested in using code and decision shapes to represent features of a correct solution, we keep only those shapes which appear in the vast majority of correct solutions, and filter out the rest.
- 6) **Form features:** Our goal is to define a small set of features that collectively represent a complete solution. However, the previous steps will generate tens to hundreds of code and decision shapes for a relatively simple problem like Squirrel. We therefore combine these smaller shapes into larger features using a form of hierarchical clustering. We iteratively combine any two features that most frequently

Table 1: Expert Features and Corresponding Data-Driven Features, as derived in [34].

Feature Name	Brief Description	Data-driven Analogue
E1. Procedure	Primary code inside of a procedure.	D1: Create a procedure OR a variable.
E2. Draw Anything	Able to draw anything on screen.	D8: Use a ‘repeat’ AND create a variable OR a parameter.
E3. Move ‘Square -like’	Able to move sprite in a square-like fashion.	D11: Have a ‘move’ AND a ‘turn’ in a ‘repeat’ AND have a ‘pen down.’
E4. Correctly Use Parameter	Correctly uses parameter within custom block.	D4: Have a ‘repeat’ inside a procedure.
E5. Repeat Correct # of Times	Repeats square-like movement correct number of times.	D5: Have a ‘multiply’ block with a variable OR two nested ‘repeats’.
E6. Move ‘Variably’	Movement is based on a variable not literal amount.	D10: Have a ‘move’ with a variable argument inside of a ‘repeat’.
E7. Move ‘Squirally’	Increase length to move for each side.	D7: Change a variable inside a ‘repeat’.

co-occur across student data until the size of the observed state-space defined by the features starts to decrease rapidly.

7) **Represent student code by feature vectors:** Once the features are formed, we can represent a student’s current code as a vector indicating the presence or absence of each feature. A student starts with a feature state of all 0s, and a correct solution should have all features present, resulting in a vector of all 1s.

2.2.2 Step 2: Cleaning Student Code

To extract good example pairs from prior student traces, we need to first remove excess blocks which do not contribute to a correct solution, as these may distract students and make examples harder to interpret. Identifying the excess blocks can be difficult, especially for intermediate partial solutions, since students can construct solutions in a large variety of ways [21, 24]. We address this by leveraging the features we defined in step 1 to exclude *irrelevant code*, which does not belong to any feature. Specifically, our cleaning procedure removes one node from the abstract syntax tree at a time (including all its children), then checks whether removing this node causes a currently completed feature to become incomplete. If removing a node “breaks” a feature, we assume that it is necessary and add it back; otherwise, we remove it. We also check to make sure removing the node does not break any code dependencies, such as deleting a variable declaration when the variable is used elsewhere. We iterate over every node in a recursive, breadth-first manner, starting from the root node. Once this iteration stops, it produces a cleaned partial solution, where all irrelevant code has been removed. We apply this cleaning procedure to *all* snapshots in correct solution traces. With well-defined features, this process can effectively clean a large variety of both partial and complete solutions, ensuring that all remaining code is useful. We use this process both for cleaning code and for extracting example pairs, as described in the next step.

2.2.3 Step 3: Extract Example Pairs

Our goal is to create a database of correct, meaningful, and self-contained example pairs to offer as feedback to students. Naively, we could extract a single example pair for each feature from each correct code trace, since each student completed each feature at least once. However, we want to generate as many example pairs as possible, so that the algorithm can adaptively select one that is similar to another

student’s code. We therefore developed a method to generate many “synthetic” example pairs, each consisting of a pair of code states $(c_0, c_1)_i$, from any cleaned student code trace. Recall that each pair should cleanly demonstrate the completion of exactly one feature by contrasting a “start code” state (c_0) and an “end code” state (c_1). The algorithm first extract one example pair each time a student completes a feature f_i , with c_1 defined as the snapshot right after f_i was completed, and c_0 as the snapshot right after the *prior* feature f_{i-1} was completed. We generate additional example pairs from each cleaned snapshot in a student solution trace with the following procedure. For each snapshot, the algorithm labels it as an end state, c_1 . It then removes exactly one data-driven feature from c_1 to create a c_0 , and together these form the example pair. This feature removal is accomplished using the code cleaning procedure described above; however, instead of removing irrelevant nodes, we use it to remove whole features. The algorithm first tries to remove one leaf node, l_i , at a time. Since the snapshot has already been cleaned, removing this node will either create an invalid code state, or cause a feature to become incomplete. In the later case, the cleaning procedure was run to remove all other code associated with the removed feature. The resulting cleaned code becomes the c_0 for the example pair, and our cleaning procedure guarantees that c_0 will have exactly one less feature than c_1 . The $(c_0, c_1)_i$ pair is added to a list which stores our example pairs. The algorithm then repeats this process recursively on c_0 , which becomes the c_1 for new example pairs, until no new pairs can be generated. In this case, we generate many example pairs per *snapshot* in a solution trace. While some are redundant, many are unique.

2.2.4 Step 4: Select an Example Code Pair

When a student requests help, we aim to provide them with the most appropriate example pair in our database as feedback. We define two ways that we can identify this example pair: 1) a **Data-Driven Features (DDF)** approach, using an algorithm to select the best example pair, or 2) an **Data-Driven Features with Interactive Selection (DDF-IS)** approach, giving the student the information needed to select an example pair. We first consider the DDF approach, in which we attempt to select the example pair which is most similar to the current student’s code. Based on this selection criteria, the selected example code pair should be very similar to the student’s code, with the goal of minimizing

the effort needed to process the “start code” and allowing the student to focus on the feature demonstrated by the example pair. In this study, for the DDF feedback, we selected an appropriate example code pair as follows:

Generate proper example pair candidates: To filter out inappropriate pair candidates based on the student’s completed features, we select only those example pairs whose “start code” has the same features as the current student code, from the example pair lists (generated in Section 2.2.3). If we cannot find any, we sort the example pairs by the Hamming distance between the feature states of “start code” and student’s current code. Then we select the example pairs with the closest start-state to student’s current code. If there are multiple example pairs available (they all have the same start state), we use the SourceCheck algorithm to sort the example pairs based on the similarity between the “start code” and student’s current code.

Select one example pair from candidates: We iterate over the example pair candidates and select exactly one pair, which accomplishes a feature that the student has not finished yet, preferring features that the majority of students in a state similar to the current student will take next.

To generate *interactive* example-based feedback, we need a way to communicate to the student which features have an available example that they can request. By default, our features are unlabeled (having been generated automatically from data), but with a small amount of instructor effort (about 3 minutes), they can be labeled. By viewing the code shapes required by each feature, an instructor familiar with the problem can generate a short, human-readable description, such as “move the sprite using a variable”, or “make the sprite move further each time”. These options can then be shown to a student. Once the student has selected a feature for an example, we select an appropriate example pair that accomplishes that feature with start code matching the student’s current feature state. If there are multiple options, we use the same criteria as in DDF: select the example pair with the most similar start state to the student’s code, which contains a proper subset of the student’s features. Note that unlike in DDF, a student *could* request an example for a feature that they have already completed. Students might decide to do this when they are unsure if they have completed a feature correctly and want to see an example for confirmation.

2.3 Expert Evaluation

To test the feasibility of our method before building the whole system and conducting a user study, we did a preliminary expert evaluation of our algorithm. We generated example pairs to support student code snapshots from our historical dataset and evaluated their quality. To simulate real student help requests where an example might be needed, we selected snapshots that corresponded to times when historical students requested hints from iSnap. As in prior work on evaluating feedback [22], we sampled up to two hint requests (and their corresponding student code snapshots) from each student. We sampled 50 hint requests in total including 20 in F16, 20 in S17, and 10 in F17. For each hint request we generated four example code pairs using different techniques: DDF, DDF-IS, and our two baselines, Student and

Expert (explained in the next section). For the examples derived from student data (DDF, DDF-IS, Student), we generated examples using semester-based 3-fold cross-validation. For each semester, we used the other two semesters’ data as training data to generate the examples. We derived 9, 9, and 10 data-driven features for F16, S17, and F17, respectively.

Two co-authors, who neither authored examples nor worked on the algorithm itself, served as experts to evaluate the generated example pairs. Both experts have extensive experience in Snap! and the Squirrel assignment. We built an interface in iSnap to present each expert with the student’s original code and the example pair. Then we asked the experts to assess the example pair based on a detailed example code rating rubric², adapted from [22]. Our rubric has 4 attributes, each rated 1, 2 or 3, with higher scores being better. These 4 attributes measured: 1) **Relevance**: how relevant the suggested example code pair is to the student’s current goals, 2) **Progress**: how well the example code pair helps students make progress towards the final correct solution, 3) **Appropriateness & Interpretability**: how likely a tutor will be to suggest this example pair to a student and how easily a novice could understand the intention of the suggested example pair and 4) **Similarity**, how similar is the “start code” to the student’s code. The first 3 attributes are meant to assess the quality of the example. The 4th is meant to help us understand the relationship between example similarity and quality, since all examples were selected based on their similarity to student code. During evaluation, experts had access to students’ code history, and based their ratings on the student’s individual context.

To ensure that the two experts had a similar understanding of the rubric, they rated 10 examples together, which were not used in this study. They then rated the 200 examples pairs used in this study in 2 rounds of 100 each³. In Round 1, they independently rated 40 example pairs and then discussed their ratings to resolve any conflicts and reach consensus. Their inter-agreement reliability across the 40 example pairs achieved squared-weighted Cohen’s kappas of 0.94, 0.91, 0.82, 0.90 for Relevance, Progress, Appropriateness & Interpretability, and Similarity, respectively, indicating very strong agreement. They then split the remaining 60 pairs and rated them individually⁴. In Round 2, one expert rated the remaining 100 pairs individually, and the other expert rated 75 of these, which were discussed until consensus was reached. Across the 115 example pairs that were rated by both experts, the total squared-weighted Cohen’s kappa was 0.77.

2.3.1 Baselines

We compare both the interactive and non-interactive data-driven example-based feedback against two baselines: Expert-authored examples and examples generated naively from Student data. For data-driven example-based feedback, we use the two strategies (DDF and DDF-IS) described in section 2.2.4. Our goal for the **Expert baseline** was to reflect

²Available at: <http://go.ncsu.edu/edm2019-rubric>

³Due to the order in which examples were generated, Round 1 included DDF and Expert examples, and Round 2 contained Student and DDF-IS examples. However, raters were blind to the condition of the example.

⁴The rated examples were in DDF and Expert conditions.

a straightforward way of generating example-based feedback using a small number of expert-authored example pairs, which an instructor might reasonably create. This corresponds to the Next Step of the Nearest Sample Solution (NSNSS) strategy introduced by Gross et al. [9], which they found to be optimal. This strategy selects the next step of the nearest expert solution. To generate expert example pairs, two experts (specifically, two co-authors who did not rate the example pairs during evaluation) manually authored example pairs for *all* steps in the most common solution paths, which at least 10% of students took to solve the problem. Each of the two co-authors created the example code separately, based on the understanding that the example code should be useful to students and no extra explanations will be used to help students understand the suggested example code. During this process, the experts could review as many students' code (including all the history) as they needed. Afterwards, they met and discussed all the example pairs that they authored and came to consensus on the example pairs. In the Squirrel assignment, the common solution graph has 14 nodes and 13 edges, of which 7 were on a primary solution path and 6 were on two alternative paths. To select an Expert example-pair for a student, we first used the SourceCheck algorithm to sort the Expert example pairs based on the size of the "start code" and the similarity between their "start code" and the student's current code. We select the example pair whose "start code" accomplishes fewer features than the student's code and is very similar to the student's code.

It may seem unfair to compare the Interactive Data-driven examples to (non-interactive) Expert examples. However, we note that it would not be reasonable to create an *Interactive*-Expert baseline. Since the Expert examples consist of a small number of hand-authored examples, which completed features in a specific order (e.g. Feature 1 is *always* completed before Feature 2), it is not reasonable to give a student the option of selecting a desired example. If the student has only completed 2 features, they could simply select the example for the final feature and see a full solution. Since the goal of example-based feedback is to show only a single, incomplete feature, we always selected the closest Expert example-pair to the student's current code. By contrast, our data-driven approach generates enough example-pairs that we are able to provide many choices of features to complete, without revealing any other features in the process.

Our goal for the **Student baseline** was to reflect a naive approach to extracting examples from student code, without the feature-based cleaning and selection of our own algorithm. Gross et al. [9] defined their baseline of student-derived examples to show only students' submitted solutions, essentially giving away the whole answer. Instead, our baseline extracts multiple examples from students, based on when they ran their code. We hypothesized that students often run their code when they have completed a meaningful feature, making this a meaningful way to demarcate examples. We extracted examples from all correct student solution traces that did not request help. We selected student code snapshots based on when they ran their code. We treated consecutive run events within 15 seconds of one another as a single run event, and we took the last of these events as the boundary between example pairs. For each

consecutive pair of run events (more than 15 seconds apart), we extract an example pair consisting of the two corresponding snapshots. The code snapshot that happened earlier serves as the "start code" of the example pair, and the one happened later serves as the "end code". When selecting an example pair to show as feedback for a given student, we used the SourceCheck algorithm to find the nearest "start code" and present that example pair as feedback.

3. RESULTS

We structured our analysis around the following research questions: **RQ1**: Can we create useful example-based feedback naively from student data, without a data-driven algorithm? **RQ2**: How does the quality of data-driven example-based feedback compare with that of expert-authored example-based feedback? **RQ3**: Can the quality of data-driven example-based feedback be improved if an example is selected interactively, rather than automatically?

We address each RQ by comparing the quality of example-based feedback generated by four feedback approaches explained above: 1) Expert-authored (Expert), 2) Naive Student Data (Student), 3) Data-Driven Features (DDF), and 4) Data-Driven Features with Interactive Selection (DDF-IS). We evaluated quality in terms of Relevance, Progress, and Interpretability, as explained above. For RQ1, we hypothesized that our results would be consistent with Gross et al. [9] that naively extracted student examples would not lead to high-quality feedback. For RQ2, we hypothesized that data-driven example-based feedback would be more relevant to the student's code than expert feedback and just as useful otherwise. For RQ3, we hypothesized that interactive selection would improve the quality of data-driven example-based feedback.

3.1 Feature Coverage

From 106 student solution traces, the DDF algorithm was able to generate 13,927 unique data-driven examples, as shown in Table 2. Of these, only 728 (5%) were derived directly from a student's trace, and the rest were generated with the recursive algorithm explained in Section 2.2.3. It took around 10 minutes (645 seconds) to generate all the data-driven example pairs. Table 2 shows the number of examples generated by each algorithm. It also gives the "snapshot coverage" and "hint request coverage" of each algorithm. The former refers to the percent of all observed snapshots which had an available example in the same feature-state (meaning the example started with the same set of features completed). For this calculation, we used the expert-authored features defined in [34]. Hint request coverage considers only the 50 hint request snapshots we evaluated. These numbers are averaged across the 3 semesters.

Table 2: Total number of generated example pairs, corresponding average snapshot coverage and hint coverage in the expert-defined feature space.

Algorithm	DDF & DDF-IS	Stud.	Exp.
# of examples generated	13,927	242	13
Snapshot coverage	0.843	0.670	0.709
Hint request coverage	0.821	0.709	0.687

3.2 Expert Ratings

Our dataset consists of 50 hint requests and 200 example pairs (one example pair per feedback approach for each hint request). All the example pairs were rated on four attributes on a scale of 1-3: Relevance, Progress, Appropriateness & Interpretability, and Similarity, as described in Section 2.3. We found the first three attribute ratings showed significant positive pairwise Spearman correlations ranging from 0.51 to 0.81 (all $p < 0.001$). Similarity also had a lower, positive correlation with the other attributes, ranging from 0.24 to 0.34 (all $p < 0.001$). Due to the high positive correlation of the Relevance, Progress, and Appropriateness & Interpretability attributes, we also compute a Quality attribute, which sums all three attributes, with scores ranging from 3 to 9. Because all 4 example-based feedback approaches selected examples using SourceCheck’s code similarity function, we also investigated the relationship between SourceCheck’s calculated similarity and the expert-rated Similarity. We found a significant, positive correlation ($\rho = 0.29; p < 0.001$), suggesting that the similarity function is reasonable but could be improved. Table 3 reports mean values of each attribute for each example-based feedback approach⁵.

Table 3: Mean attribute ratings (with standard deviation) for example pairs in from each approach.

N = 50	Relev.	Prog.	A.&I.	Qual.	Simil.
DDF-IS	2.62 (0.73)	2.46 (0.76)	2.22 (0.82)	7.30 (2.05)	2.22 (0.86)
Expert	2.24 (0.89)	2.36 (0.80)	2.14 (0.90)	6.74 (2.24)	2.18 (0.80)
DDF	2.12 (0.92)	2.06 (0.89)	1.84 (0.82)	6.02 (2.38)	2.28 (0.88)
Student	1.72 (0.90)	2.12 (0.90)	1.80 (0.86)	5.64 (2.20)	2.24 (0.87)

To address our research questions, for each attribute we used Kruskal-Wallis test to determine if there was a significant difference in ratings across feedback generation approaches. For the overall Quality attribute, we found a significant difference among conditions ($\chi^2(3) = 16.06, p < 0.001$). We performed a post hoc Dunn’s test with Benjamini-Hochberg correction for multiple comparisons⁶ [2, 5] to identify pairwise significant differences between approaches. This showed a significant difference between Expert and Student examples ($z = 2.48, p = 0.026, r = 0.25^7$), DDF and DDF-IS ($z = 2.76, p = 0.017, r = 0.28$), DDF-IS and Student ($z = 3.69, p = 0.0013, r = 0.37$), suggesting that for overall quality, Student < DDF < DDF-IS, and Student < Expert.

We then inspected the difference for each individual attribute. A Kruskal-Wallis test showed a significant difference among approaches for the Relevance ($\chi^2(3) = 24.45, p < 0.001$). A post-hoc test using Dunn’s test with Benjamini-Hochberg correction showed a significant difference between

DDF and Student ($z = 2.14, p = 0.049, r = 0.21$), Expert and Student ($z = 2.79, p = 0.016, r = 0.28$), DDF-IS and DDF ($z = 2.76, p = 0.011, r = 0.28$), DDF-IS and Student ($z = 4.90, p < 0.001, r = 0.48$), DDF-IS and Expert ($z = 2.11, p = 0.04, r = 0.21$), but we did not find a significant difference between DDF and Expert ($z = 0.65, p = 0.515, r = 0.07$). This suggests that for Relevance, Student < DDF = Expert < DDF-IS.

We also found a significant difference among conditions for the Appropriateness & Interpretability ($\chi^2(3) = 8.98, p = 0.030$). However, a post-hoc test using Dunn’s test with Benjamini-Hochberg correction did not find any pairwise significant differences between conditions. For the other two attributes, similarly, we did not find any significant difference between conditions: Progress ($\chi^2(3) = 7.14, p = 0.068$); Similarity ($\chi^2(3) = 0.62, p = 0.89$). The results suggest that DDF-IS example pairs are more relevant to student code and are equally helpful and interpretable compared with expert-authored examples.

3.3 Inspection of Examples

To better understand our quantitative results, we manually inspected examples generated by each approach to understand how they differed and how those differences impacted the expert ratings. We investigated the following questions and present situations that highlight possible answers:

Why does the naive Student baseline have low quality? Our quantitative results show that our naive Student baseline does not produce useful example pairs. We manually investigated some Student example pairs to better understand why. Recall that the Student baseline extracts examples showing the changes between consecutive run of student code. We derived 242 of these example pairs across 3 semesters from 39 correct student submissions that did not request hints. Upon inspection, it is clear that this segmentation approach did not always produce meaningful example pairs. For example, a Student example pair might simply rearrange the order of some code blocks. This is a common debugging behavior, but it does not usually yield a useful example. We also found that even when Student example pairs demonstrated a meaningful step, they were often selected for students who had already completed that feature. This is not surprising, since the Student baseline selected the example with the most similar start code, but this does not guarantee the student will not have additional features completed. Lastly, many Student examples contained extraneous code that made them harder to interpret. These three problems – lack of meaningful steps, repeating completed steps, and extraneous code – are all addressed in our DDF-based example selection. With good features, we can identify meaningful example steps, ensure that all examples complete new features, and remove extraneous code.

When were data-driven examples more adaptive than Expert examples? Our quantitative results suggest that the DDF-IS approach was able to generate examples that were significantly more Relevant than those of the Expert approach. We hypothesized that this was enabled by the large number of unique example pairs generated by DDF (13,927). By contrast the Expert approach used only 13 examples pairs, which covered the common solution paths

⁵Although attribute ratings are ordinal, we report the mean and SD, since the median values for each attribute are generally the same (2 or 3)

⁶We report p-values corrected with the Benjamini-Hochberg procedure to control the false discovery rate at 0.05, keeping the α significance threshold at 0.05.

⁷The effect size r is calculated as described in [25]

Student Code	DDF-IS	Expert
<pre> Squirrel(rotations, length): Clear() PenDown() Repeat(4 * rotations) Move(10) Turn(90) Change(length)by(25) </pre>	<pre> Squirrel(rotations, length): PenDown() Repeat(4 * rotations) Move(10) Move(rotations) Turn(90) Change(length)by(5) </pre>	<pre> - DrawSquirrel(): + DrawSquirrel(rotations): PenDown() Repeat(4) Repeat(rotations) Move(10) Turn(90) PenUp() </pre>

Figure 3: DDF-IS and Expert examples for one snapshot (red/green indicate changed code in the example).

that at least 10% of students took to solve the problem. While some of DDF-IS’s improvement may have come from its Interactive Selection step (explored below), our results in Section 3.1 also show DDF examples have larger coverage than the expert-authored examples for both the hint requests and student snapshots. Our manual inspection uncovered a number of situations when a relevant expert Example was not available, but a DDF example was. For example, a strong minority of students solved the Squirrel problem by using a second input (parameter) to store the side length of shape. Figure 3 shows that for the same hint request, the DDF-IS can suggest examples not only similar to the student code, but also relevant to what the student is working on. However, the expert-authored example only has one parameter in the custom block and suggests something that the student has already done. The Expert example becomes less helpful and irrelevant when a student has solution that deviates from the Expert examples. However, our data-driven examples are more adaptive in this scenario and can provide examples both similar and relevant to the student. We note that this adaptivity was enabled in large part by the recursive example generation algorithm outlined in Section 2.2.3. Only 2 of the 50 examples selected by DDF-IS were extracted directly from student code traces (the “naive approach”); the other 48 were generated synthetically.

When did DDF-IS select better examples than DDF?

Since DDF and DDF-IS were selecting examples from the same pool of examples, but DDF-IS has significantly higher overall quality, we wanted to understand where the selection algorithms differed. We investigated some pairs and focused on when our algorithm failed to select relevant examples. In those scenarios, we found that the DDF would suggest the student to add a ‘pen down’, or add a custom block in the main script area. Those features are necessary for a correct solution, but they may have lower priority compared with other features such as “control the sprite to draw a square” or “repeat the spiral the correct number of times.” Additionally, we also found that the data-driven feature detector sometimes counted a feature as complete when it still had a bug or a missing block. Thus, it would suggest example pairs that accomplish new features without fixing the broken one. In the opposite case, the student may have already finished a feature, but the feature detector sometimes failed to detect it, showing a redundant example. This occurred frequently when students accomplished a feature in a unique way, not captured by our data-driven feature definition. For example, a few students attempted to use a recursive approach to solve Squirrel, but since this was quite uncommon, our data-driven features failed to generate meaningful example pairs for this solution. The DDF-IS can help resolve the first two cases, since students can choose whether they

need help on a feature that the DDF failed to detect.

4. DISCUSSION

RQ1: Can we create useful example-based feedback naively from student data, without a data-driven algorithm? Our results suggest that naively extracting examples from student code based on when students ran their code does not yield high-quality example-pairs. These naive Student examples were lowest or second-lowest, rated on every dimension, with significantly lower Relevance than all other approaches and significantly lower overall Quality than the DDF-IS approach and the Expert-authored examples. This is consistent with our hypothesis for RQ1. It is also in agreement with the work of Gross et al. [9], who found that using student solutions as example-based feedback were rated lower by experts and led to less improvement in students than other, expert-authored examples. However, rather than using a student’s submitted code as an example as Gross et al. did, we used the changes that students made between running their code. We believe that this represents a more reasonable student baseline, since it only shows a part of the answer like the other feedback approaches. It should also theoretically limit the cognitive load needed for students to learn from the examples. Our results show that even so, a naive approach does not create high-quality student examples, compared to other approaches. Our data-driven approach attempts to address this by creating examples based on when students completed features.

One of the goals of using student data to generate examples is that they can more closely match the student’s current code. In fact, we were able to extract 242 unique Student examples, compared with 13 for the Experts. This did enable our system to identify Student examples that were more *Similar* to the help-requesting student’s code than Expert examples (though not significantly more). However, it is also clear that Similarity alone did not translate into Relevance, since the Student examples had the lowest Relevance scores. We cannot guarantee that students make meaningful changes between two consecutive snapshots, and thus the generated example pairs may not accomplish a meaningful chunk of code. For example, the Student example pair may suggest something that a student has already done. In this case, we could use the data-driven features to identify a later snapshot with more relevant changes as the “end code.” This suggests the need for a more deliberate, data-driven process that can still create a large number of examples to select from without sacrificing quality.

RQ2: How does the quality of data-driven example-based feedback compare with that of expert-authored example-based feedback?

We hypothesized that our Data-Driven Features (DDF) examples would be more relevant to help-requesting student’s code than the expert baseline, with similar levels of Progress and Interpretability. However, our results did not support this hypothesis. There were no significant differences between the two approaches, with the DDF algorithm performing similarly on Relevance and slightly worse on Progress and Interpretability. Our original hypothesis was based on the premise that data-driven examples would be more Relevant, since they are selected from a much larger database of examples (4,000 to 5,000) that represents a large variety of student code. While this was

not confirmed, our results do suggest that our current, *non-interactive* data-driven algorithm performs significantly better than naive Student examples and only marginally worse than Expert examples. Since it is often difficult to get instructors to author examples [12], this suggests our DDF examples should be a reasonable substitution.

There are a few possible explanations for the poorer performance of DDF. First, it is possible that Squirrel problem we analyzed may not have been complex enough to necessitate generating a large variety of examples, which is one of the key proposed advantages of our algorithm. If most hint-requesting students performed the steps of the problem in the same order as the Expert examples, these Expert examples would generally be Relevant, leaving less room for the DDF examples to improve upon them. We have some support for this explanation, since across semesters 53.8% to 85.7% of the hint requests we analyzed had an expert feature state that matched one of our Expert examples exactly. However, we also note that the expert baseline was rated less than 3 for Relevance 46% of the time, so there was clearly room for improvement, as we discuss later.

It is also clear that the DDF approach did not perform as well as expected, scoring between the Expert and Student baselines for Progress and Interpretability. There are two possible explanations for this: either the algorithm is failing to *generate* good example pairs, or it is generating useful example pairs, but failing to *select* the best pair to show a given student. The higher scores of the DDF-IS algorithm, which generated the same example pairs as DDF, but allowed a human to select the best one, suggest that the problem lies in the DDF algorithm's selection of example pairs. This selection process (explained in Section 2.2.4) primarily uses the SourceCheck algorithm to identify the example with the most similar start state to the student's code. While this approach did lead to DDF having the highest Similarity ratings, there was only a $\rho = 0.238$ correlation between Relevance and Similarity. This suggests that Similarity alone is not a good proxy for example Relevance or overall quality. The challenge of automatically selecting an appropriate example also reflects prior work on data-driven feedback [23], where low-quality hints arose because the hint generation algorithm was unable to identify the most useful hints and filter out less useful hints.

RQ3: Can the quality of data-driven example-based feedback be improved if an example is selected interactively, rather than automatically? Our results show that the quality of data-driven example-based feedback can be improved if the examples are selected interactively. The DDF-IS algorithm scored significantly higher than the DDF algorithm on Quality and Relevance, even significantly outperforming the expert baseline on Relevance, with the best overall scores. Recall that for the DDF-IS examples, we manually tagged the data-driven features with natural language labels, which a student could reasonably select from when making an example request. In this preliminary evaluation, we simulated this selection process by manually selecting the best *data-driven feature* to show to each student. Importantly, we only selected the feature (e.g. “move the sprite using a variable”), not the example, and the algorithm still selected the best possible example for a given feature

(from hundreds of possible choices). Still, it is likely that an expert familiar with the system is more likely to choose an appropriate feature than a student, so this represents an *upper bound* for how well an interactive, data-driven example selection algorithm could reasonably perform. These results show that, when this proper selection is applied, the larger database of example pairs generated by our algorithm can lead to more Relevant examples than a static set of expert-authored examples. This represents a growing trend among data-driven systems that support programming to leverage human (i.e. student and instructor) knowledge in conjunction with data-driven algorithms [10, 18, 33]. However, from our preliminary expert evaluation, we can not make claims about how students would actually react to such a choice. Our results also suggest ways that we can improve the *automated* example selection procedure. The majority of low-quality DDF example pairs would select a feature that the student needs but could be less relevant than other features. For example, one example pair suggests adding the student's custom block into the main script so they can test it. However, in Snap!, students can click on the custom block to test it directly. This feature should therefore have lower priority than others. For the example shown in the Results section, the data-driven feature detector failed to detect correct variations in student code, and suggested a feature that the student had already completed. These examples suggest that it may be more important to select the most important feature to demonstrate, before considering the similarity of the example to the student's current code.

5. CONCLUSION

This study presents a method to generate data-driven examples automatically from historical student data. We evaluated two versions of data-driven generated examples using the student code when they need help, compared with two baselines: examples authored by experts and examples derived naively from student solution traces. Experts evaluated all of the example pairs based on a multidimensional rubric. Our preliminary results demonstrate that by selecting appropriate features, our data-driven examples can be more relevant than both baselines while retaining the usefulness and interpretability. These promising results suggest that our method can generate adaptive, data-driven examples automatically with quality similar to that of expert-authored examples. Even though our method is based on a block-based programming environment, it is language-agnostic and may also be generalized to textual programming languages; though further studies are needed to verify this proposed generalizability.

Limitations: This preliminary study relied on experts ratings to assess example quality, yielding valuable insight, but future work is needed to determine whether these results translate into improved student performance and learning. For example, even a well-rated example pair may still give away too much of the answer and impede learning. We also do not know how our results will generalize beyond the single assignment evaluated here, since we only applied this method to a short, block-based problem with a solution that is usually 7-10 lines of code. In our DDF-IS condition, we had an expert interactively select the feature to be presented, rather than a student. As noted earlier, this is likely an optimistic implementation, as we do not know

whether students can effectively select examples. Finally, all conditions used the SourceCheck algorithm to select similar examples to the student's code, but other approaches may better capture example relevance (e.g. [11]). We are currently planning a student evaluation of the DDF algorithm to address these limitations.

ABSTRACT

The Elo rating system has been recognised as an effective method for modelling students and items within adaptive educational systems. The existing Elo-based models have the limiting assumption that items are only tagged with a single concept and are mainly studied in the context of adaptive testing systems. In this paper, we introduce a multivariate Elo-based learner model that is suitable for the domains where learning items can be tagged with multiple concepts, and investigate its fit in the context of adaptive learning. To evaluate the model, we first compare the predictive performance of the proposed model against the standard Elo-based model using synthetic and public data sets. Our results from this study indicate that our proposed model has superior predictive performance compared to the standard Elo-based model, but the difference is rather small. We then investigate the fit of the proposed multivariate Elo-based model by integrating it into an adaptive learning system which incorporates the principles of open learner models (OLMs). The results from this study suggest that the availability of additional parameters derived from multivariate Elo-based models have two further advantages: guiding adaptive behaviour for the system and providing additional insight for students and instructors.

1. INTRODUCTION

Adaptive educational systems make use of data about students, learning process, and learning products to adapt the level or type of instruction for each student. Commonly, this adaptivity takes the form of selecting items from a large repository of learning resources to match the current learning ability of a student [17]. To do so, adaptive educational systems rely on learner models that capture an abstract representation of a student's ability level based on their performance and interactions with the system [6]. Two conventional approaches have been heavily studied for modelling learners. (1) Bayesian Knowledge Tracing (BKT) uses

a Hidden Markov Model for capturing students' knowledge state as a set of binary variables indicating whether a knowledge component has been mastered [4]. (2) Item Response Theory (IRT) [11] and its extensions such as Additive Factor Model (AFM) [3] and Performance Factor Analysis (PFA) [18] rely on a logistic regression model to estimate latent traits related to students' knowledge state and the difficulty of learning items. Neither of these approaches, however, can be easily integrated into online adaptive educational systems as they generally require pre-calibration on big samples of data and ongoing addition of new students and new learning items to the system necessitates continuous calibration of model parameters [19].

The Elo rating system has been shown to be an effective alternative to the above mentioned conventional approaches for modelling students in adaptive educational systems [14]. It is simple, fast, robust and order-sensitive which makes it a suitable model for adaptive educational systems where it is required to update students' proficiency level upon administration of each question [23]. In the educational context, the Elo-based model is employed to conduct a paired comparison among students and learning items as competitors [23]. This model is self-correcting, meaning that the ratings, in the long run, should correctly reflect students' knowledge states and difficulty levels of questions [20].

The majority of the existing studies on Elo-based models have the following two characteristics: They (1) use repositories that contain items that are pure [9] and are tagged with a single concept and (2) are studied in the context of adaptive testing systems such as computerised adaptive testing (CAT) [5]. The contribution of this paper lies in (1) introducing a new variant of the Elo-based algorithm called M-Elo that has the capacity to model students and items using repositories that contain items that are tagged with one or more concepts, and (2) investigating its fit in the context of adaptive learning systems, which in contrast to adaptive testing systems, take a more student-centred approach with the aim of assisting students in their learning.

To evaluate the applicability of M-Elo in the context of adaptive learning where learning items are explicitly tagged with one or more concepts, we first compare the predictive performance of M-Elo against the standard Elo-based model using simulated data sets. The results from these experiments demonstrate that the behaviour of the M-Elo is consistent

Solmaz Abdi, Hassan Khosravi, Shazia Sadiq and Dragan Gasevic "A Multivariate ELO-based Learner Model for Adaptive Educational Systems" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 228 - 233

with expectations over a range of parameter settings, and therefore this provides some evidence to suggest that it will be robust in a real-world setting. We then compare the predictive performance of M-Elo against the standard Elo-based model using public data sets. The results from the experiments indicate that M-Elo have superior predictive performance compared to the standard Elo-based model, but the difference is rather small. Finally, we integrate M-Elo into an adaptive learning system and conduct a case study by piloting this system in a large introductory course on relational databases at The University of Queensland.

The results obtained from our case study suggests that using M-Elo, as a multivariate Elo-based model, in adaptive learning systems have two additional advantages beyond the standard Elo-based model: The first advantage lies in the availability of additional parameters that provide insight into the characteristics of the domain and the learning process which in turn can be used for guiding adaptivity. The second advantage is that when M-Elo is opened based on the concepts of open learner models (OLMs) [2], it can provide additional insight on course level and individual level competencies and gaps, that can be used by instructors for improving learning item design, while also providing meta-cognitive benefits for students, such as increased motivation and trust in the system. The conducted case study also revealed some of the shortcomings of using Elo-based models in the context of adaptive learning. The main issue is that Elo-based models consider items and students as identical rivals. This assumption seems to fail to adequately model the long-term use of an adaptive learning system in which students' knowledge may increase over time while the difficulty level of the items remains constant.

2. BACKGROUND

Elo-Based Learner Models. The Elo rating system is originally developed to rate chess players and is established based on paired comparison of data where two chess players compete against each other [23]. In the educational setting, a similar paired comparison can be conducted between a student and a question being attempted by the student. The standard implementation of the Elo-based model in education resembles the Rasch model employed in IRT that models students and questions with a single global parameter [20]. An important extension to the Elo-based model in education is the multivariate Elo-based model proposed by [9] in the context of psychometrics, where instead of using a global knowledge parameter for students, it uses an overlay model which estimates the competency of a student in each different concept using a separate parameter. A similar model for adaptive practice of facts was later proposed by [20], which had an additional global parameter compared to the multivariate Elo-based model that was used in combination with the concept level parameters in modelling the ability of a student on each concept. Both of these models make the assumption that items are tagged with a single concept, which limits their applicability in domains where items can be tagged with multiple concepts. For example, in a Programming domain, an arbitrary learning item might be associated with both "lists" and "loops" concepts. M-Elo, our proposed model, is an extension over the multivariate Elo-based model that has the capacity to model students and items in the presence of items with multiple concepts.

Adaptive Testing vs. Adaptive Learning. Adaptivity in educational systems has been investigated broadly both in the context of computerized adaptive testing (CAT) and adaptive learning [17]. Generally, adaptive testing systems conduct an exam using a sequence of questions that are successively administered with the purpose of maximising the precision of the system's current estimate of the student's ability. The exam is usually terminated once the system has an estimate of the student's ability with a confidence level that exceeds a user-specified threshold. In contrast, adaptive learning systems such as ALEKS¹ take a more student-centred approach with the aim of assisting students in their learning. As such, in most adaptive learning systems, students (1) have the opportunity to decide whether or not to engage with the suggested learning items, (2) can spend, theoretically, an infinite amount of time on a learning item or on the system and (3) will receive rich feedback on their learning after engaging with each learning item. In this paper, we examine the fit of our proposed model, and more generally multivariate Elo-based models in the context of adaptive learning.

Open Learner Models. Open learner models (OLMs) are learner models that are externalised and made accessible to students or other stakeholders such as instructors, often through visualisation, as an important means of supporting learning [2]. They have been integrated into a variety of learning technologies such as learning dashboards [1], intelligent tutoring systems [21] and adaptive learning platforms [8] to help students and instructors in monitoring, reflecting and regulating learning [2]. In this paper, we investigate the benefits of opening Elo-based models, such as M-Elo in adaptive learning system based on the principles of the OLMs.

3. ELO-BASED LEARNER MODELLING

In this section, we first define a mathematical notation for describing the models. Section 3.1 then provides a review of the standard Elo-based model in the educational context. Finally, Section 3.2 introduces our proposed variation of the multivariate Elo-based model, which we call M-Elo.

In what follows, let $U_N = \{u_1 \dots u_N\}$ denote a set of students who are enrolled in a course on an adaptive educational system, where u_n refers to an arbitrary student. Each course consists of a set of concepts $\Delta_L = \{\delta_1 \dots \delta_L\}$, referred to as the domain model, where δ_i presents an arbitrary concept. In this work, the notion of a concept is based on taxonomies of knowledge components described by [16]. Let $Q_M = \{q_1 \dots q_M\}$ present the content model, denoting a repository of learning items that are available to students in a course in the adaptive learning system, where q_m refers to an arbitrary item. These learning items can be tagged with one or more knowledge components; $\Omega_{M \times L}$ is a two-dimensional array, where ω_{ml} is $1/g$ if item q_m is tagged with g knowledge components including knowledge component δ_l , and 0 otherwise. Let a two-dimensional array $A_{N \times M}$ keep track of students' attempts on the items, where $a_{nm} = 1$ indicates that student u_n has answered item q_m correctly, and $a_{nm} = 0$ indicates that student u_n has answered item q_m incorrectly.

¹<https://www.aleks.com/>

3.1 The Standard Elo-based Learner Model (Elo)

In the standard Elo-based learner model (Elo), both students and items are considered as identical rivals. Elo assumes one student parameter θ_n indicating u_n 's global proficiency level on the entire domain and one item parameter d_m presenting the difficulty level of item q_m . It uses a logistic function to estimate the probability of a correct answer by a student to a given item based on the difference between the student's global proficiency level and the item's difficulty. [20]:

$$P(a_{nm} = 1 | \theta_n, d_m) = \sigma(\theta_n - d_m) \quad (1)$$

To account for the guessing effect in the case of multiple choice items with c possible options, Formula 1 can be easily replaced with a shifted logistic regression using: $P(a_{nm} = 1 | \theta_n, d_m) = \frac{1}{c} + (1 - \frac{1}{c}) * \sigma(\theta_n - d_m)$. once u_n has attempted q_m , the knowledge state of u_n and difficulty level of q_m are simultaneously updated using the following formulas:

$$\theta_n := \theta_n + K(a_{nm} - P(a_{nm} = 1 | \theta_n, d_m)) \quad (2)$$

$$d_m := d_m + K(P(a_{nm} = 1 | \theta_n, d_m) - a_{nm}) \quad (3)$$

, where K is a constant value determining the sensitivity of the estimations based on the student's last attempt. The updates to the student's knowledge state (Formula 2) and the difficulty of the item (Formula 3) in Elo follows the principles of zero-sum game, in which the sum of gains (loss) to the student's knowledge state and the loss (gain) to the difficulty of the item after the student answers the item turns out to be zero. In most extensions of the Elo-based models, in order to get to a stable estimations for the student's knowledge state and item difficulty, K is replaced with an uncertainty function

$$U(n) = \frac{\gamma}{1 + \beta * n} \quad (4)$$

, where γ and β are constant hyper-parameters determining the starting value and slope of changes, respectively, and n indicates the number of prior updates on student's knowledge state or item difficulty [20].

3.2 Multi-Concept Multivariate Elo-based Learner model (M-Elo)

In contrast to Elo, where only one parameter is used to model a student's knowledge state on the entire domain, M-Elo uses independent parameters to model the student's knowledge state on each individual concept in the domain, and a global parameter for modelling each item. As in Elo, for each learning item q_m there is a global difficulty d_m approximating the difficulty level of the item. For students, let a two-dimensional array $\Lambda_{N \times M}$ represents a student's Elo-based learner model, where λ_{nl} represents student u_n 's knowledge state on concept δ_l , approximating the proficiency level of the student on that certain concept. To estimate the probability that student u_n answers an item q_m correctly, we first compute $\bar{\lambda}_{nm} = \sum_{l=1}^L \lambda_{nl} \times \omega_{ml}$, which estimates u_n 's average competency on concepts that are associated with q_m . We then compute the probability of u_n answering q_m correctly using:

$$P(a_{nm} = 1 | \bar{\lambda}_{nm}, d_m) = \sigma(\bar{\lambda}_{nm} - d_m) \quad (5)$$

After u_n answers q_m , the updated estimate of d_m is obtained using:

$$d_m := d_m + K(P(a_{nm} = 1 | \bar{\lambda}_{nm}, d_m) - a_{nm}) \quad (6)$$

where K can be replaced with an uncertainty function $U(n)$ presented in Formula 4. To update student u_n 's Elo ratings based on the given answer to item q_m , we update the student's parameter on each concept δ_l the question is tagged with separately using the following formula:

$$\lambda_{nl} := \lambda_{nl} + \alpha.K(a_{nm} - P(a_{nm} = 1 | \lambda_{nl}, d_m)) \quad (7)$$

where α is a normalisation factor, ensuring that the zero-sum game principles are enforced in the model. As such, the net change made to the parameters estimating u_n 's proficiency level in the concepts that are associated with q_m (computed by Formula 7) and d_m (computed by Formula 6) sum to zero. α is computed using the following formula:

$$\alpha = \frac{|P(a_{nm} = 1 | \bar{\lambda}_{nm}, d_m) - a_{nm}|}{\sum_{l=1}^L (|a_{nm} - P(a_{nm} = 1 | \lambda_{nl}, d_m)| \times \omega_{ml})} \quad (8)$$

4. EVALUATION

In this section, we evaluate the suitability of M-Elo in the context of adaptive learning systems. Section 4.1 compares the predictive performance of M-Elo against Elo using a suite of simulated data sets. Section 4.2 compares the predictive performance of M-Elo against Elo using publicly available data sets. As commonly used in the evaluation of learner models, we use the area under the curve (AUC), root mean squared error (RMSE) and accuracy (ACC) for reporting the predictive performance of the models. For all experiments, students' knowledge states and item difficulties in Elo and M-Elo are initialised to zero. Section 4.3 then reports the results of a case study that integrates M-Elo into an adaptive learning system which incorporates the principles of OLMs.

4.1 Synthetic Data Sets

Synthetic data sets were used to assess the behaviour of the models under different settings by varying parameters in the data generation template. The synthetic data sets were generated using a sequence of steps proposed by [13]. At first, a set of students with predefined knowledge states over a set of knowledge components were created. Assigning students' knowledge state was performed by sampling from a normal distribution, where the mean of distribution for each student was sampled from a uniform distribution. In this model, the standard deviation (σ) of the normal distribution determined the complexity of a student's knowledge state, where smaller values of σ led to having students that had roughly the same ability across all of the knowledge components and bigger values of σ led to having students with a higher diversity on their abilities across all of the knowledge components. Then, a set of learning items with pre-defined concepts, level of difficulty and discrimination was generated. Assigning concepts to items was performed by sampling from a discrete uniform distribution, while difficulty and discrimination were sampled from a normal distribution. Lastly, to compute the probability that a student u_n answered a learning item q_m correctly, a 2PL Item Response Theory (IRT) [10] model was used as recommended by [7] using: $\frac{1}{1 + e^{-a_m(\theta_n - b_m)}}$, where, θ_n represents a student's average competency on the concepts associated with

the item, and b_m and a_m were the difficulty level and the discrimination level of the item q_m , respectively. In all synthetic data sets, 100 students, 1000 learning item and 70,000 answers were sampled completely at random. Each learning item was tagged with one to three concepts. In these experiments, 70% of data was used for training and the remaining 30% was reserved for the test. Each experiment was repeated five times and the reported values are the average results across the five runs.

Figure 1: AUC as σ is increased. Results are reported for $L = 10$, and $L = 100$

Figure 1 compares the AUC performance of Elo and M-Elo in estimating students' knowledge states with respect to different values of σ under two different settings for the number of knowledge components (L). Our results for $L = 10$ suggest that for smaller values of σ , Elo outperforms M-Elo. This was predictable, as in this setting, each student has roughly the same competency level on all of the concepts, and since Elo relies on a global knowledge estimation for students proportional to their overall performance, it can outperform M-Elo in this setting. As σ is increased and students with more diversity in their abilities across different concepts are generated, M-Elo outperforms Elo as it is able to discriminate between students' abilities on each individual concept, leading to more accurate estimations of students' knowledge state compared to Elo. By increasing L to 100, the same trend is observable; however, the intersection point for σ where M-Elo outperforms Elo becomes bigger, as in this scenario, with the same amount of data, M-Elo needs to learn many more parameters independently. Evaluations using RMSE and ACC led to very similar patterns as AUC. Therefore, in the interest of space, figures reporting these results have not been included.

4.2 Public Data Sets

Three data sets namely 'Algebra I 2005-2006' (Alg2005), 'Algebra I 2006-2007' (Alg2006) and 'Bridge to Algebra 2006-2007' (BAI2006), which were obtained from the PSLC Datashop were used [15]. These data sets were originally obtained from Carnegie Learning's Cognitive Tutor and were made available as the "DevElopment" sets in KDD Cup 2010 [22]. Cognitive Tutor provides a fine representation of knowledge components associated with each item. It is a formative assessment tool, where each step taken by a student to answer a problem is considered as an individual interaction. Each learning item (referred to as 'Step' and presented by 'Step Name' in the data sets) is associated with one or more concept (KC) covered in the course. We used the train/test split provided by KDD Cup 2010 and discarded interactions with items that have not clearly been tagged with particular concepts. No students were discarded. Overall informa-

tion about these data sets are presented in Table 1. A grid search was conducted to determine optimal values for hyperparameters γ and β of the uncertainty function, described in Formula 4. As also reported by [20], the results were not really sensitive to changes from these parameters. In all the reported experiments on public data sets, γ was set to 1.8 and β was set to 0.05.

Table 1: Public data sets

Data Set	Students	KC	Items	multi-KC ²	Interactions
Alg2005	575	112	147,914	51,171	609,979
Alg2006	1840	714	319,151	21,415	1,825,030
BAI2006	1146	493	19,954	1,650	1,822,697

Table 2 compares the AUC, RMSE and accuracy (ACC) of the model fit statistics related to each model for estimating students' knowledge state. As it is indicated, on all three data sets M-Elo outperformed Elo in predicting student performance, but the difference was rather small. Considering the insights obtained from the experiments with synthetic data sets, where M-Elo was outperforming Elo with a small margin, it may be possible to hypothesise that students often have different competency levels on different concepts, but these differences are often not too significant.

Table 2: AUC, RMSE and ACC for public data sets

Data Set	AUC		RMSE		ACC	
	Elo	M-Elo	Elo	M-Elo	Elo	M-Elo
Alg2005	0.726	0.750	0.392	0.385	0.787	0.79
Alg2006	0.687	0.695	0.394	0.390	0.784	0.797
BAI2006	0.676	0.712	0.368	0.361	0.827	0.828

4.3 Case Study

To investigate the fit of M-Elo for adaptive learning in an authentic environment, we integrate M-Elo into an adaptive learning system called RiPPLE [12] and piloted the platform in an introductory course on relational databases at The University of Queensland. The course covers many concepts that are generally included in an introductory course on relational databases including conceptual database design using ER diagrams, relational models, functional dependencies, normalisation, relational algebra, Structured Query Language (SQL), data warehousing and database security. The platform was used for 13 weeks; during this period, 521 of the students enrolled in this course made 91,340 attempts on 1,632 learning items which were available in the system. Among these items, 144 items were tagged with two or more of the 17 concepts, which were associated with the course. Our aim was to investigate the benefits and shortcomings of using M-Elo in an adaptive system where the model is shared with the students based on the principles of OLMs through a visualisation widget, as indicated in figure 2, which allows students to visually see their current knowledge state on all concepts of the course. This visualisation is updated and represented to students as soon as they answer a new item from the item pool.

Guiding adaptivity. To guide the adaptivity of the system, the estimated knowledge states of the students and difficulties of the questions, as computed by M-Elo, are passed to the recommendation engine of the adaptive system. For each student, the recommendation engine recommends questions

²multi-KC in Table 1 indicates the number of items tagged with two or more knowledge components (KCs)

Figure 2: Overview of the OLM visualising the current knowledge state of a student.

that are on concepts where a student has the largest knowledge gap at a difficulty level that reflect the current learning ability of the student. This adaptivity at a concept-level is because of the availability of the additional parameters learned by M-Elo, which is not possible to achieve using the standard Elo rating.

Insights from student feedback. To capture students' perspectives about the model, a survey was conducted at the end of the semester using the following three statements: (1) Motivation: the visualisation used by RiPPLE for showing my knowledge state increases my motivation to study or further use the system, (2) Rationality: having the ability to visually see my current knowledge state, helps me to understand the rationale behind suggestions made by the system, (3) Trust: having the ability to visually see my knowledge state, increases my trust in recommended questions. Responses were captured using the Likert scale, where 1 represents "strongly disagree" and 5 represents "strong agree". The survey also had an open-ended question asking students for feedback on the system. Overall, 55 students who had enrolled in the course and used the system voluntarily participated in the survey. Figure 3 represents the results of the survey. The majority of students (63.6%) agreed or strongly

Figure 3: Student survey results

agreed that visualisation of their learner model in RiPPLE increased their motivation to further use the system. Furthermore, the majority of the students (61.8%) agreed that having the ability to visually see their current knowledge state helped them to understand the rationale behind recommendations made by the system and that it increased their trust in recommendations. In their written comments one student mentioned that "I have used a similar platform in the past, however, the visualisation of my knowledge state in this platform is a great improvement on those." Interestingly, two students mentioned that they lost motivation in answering easy questions as the potentially large loss of rating in answering the question incorrectly outweighed the small rating gain received in answering the question correctly. Upon closer examination, we noticed that it seemed

challenging to maintain a balance between the students' proficiency level and the learning items' difficulty level in our pilot. Throughout the semester, the average difficulty level of the learning items was falling and the average rating of the students' proficiency was rising. This can be explained by the student-centred design of the system that provided students full access to the internet, textbooks and colleagues as well as an infinite amount of time for answering a question. This may suggest that the zero-sum game principles where the net change in ratings after a student has answered a question is zero might not be ideal for adaptive learning systems. We believe that this may not be an issue for adaptive testing, where the exam-like setting of the system might balance between the students' ratings and the learning items' ratings.

Insights from instructor feedback. To capture the teaching staff's perspectives, we held informal discussion sessions with members of the teaching staff. They appreciated the additional insight on course level and individual level competencies and gaps that was provided by M-Elo; similar benefits have also been reported by [19]. For example, the learning model presented in Figure 2 indicates that at a class level, students have performed best on "ER-models" and "SQL" and have performed worst on "Map-ER-Schema" and "Map-Schema-ER" in the course presented in this pilot. A shortcoming that the teaching team has noticed was that students tended to get discouraged from using the system once they had used it for a while as they were not able to make significant changes to their knowledge state despite answering questions correctly. Upon closer examination, we realised that this is due to the use of the uncertainty function, as described in section 3 and Formula 4, which reduces the sensitivity of the estimations as the number of attempts is increased. This functionality seems to be better suited for adaptive testing rather than adaptive learning systems because of the following reason: Given that a student would often take an adaptive test in one sitting with a short timeline and receive no feedback on their work, it is common for adaptive testing systems to assume no learning has occurred during the exam, and as such use of an uncertainty function can help with stabilising the ratings; however, a student would often interact with an adaptive learning environment over a period of time and competencies might improve via receiving rich feedback on their learning or decline as a result of forgetting. As a consequence, adaptive systems commonly expect the knowledge state of the student to change significantly as they interact with the system. This means that reducing the sensitivity of the estimations over time may restrict the model from unwaveringly evolving to accurately represent the current knowledge state.

5. CONCLUSIONS AND FUTURE DIRECTIONS

The aim of this paper was to introduce a new multivariate Elo-based learner model called multi-concept multivariate Elo rating system (M-Elo) where learning items can be tagged with one or more concepts and investigate its benefits and shortcomings in the context of adaptive learning. The results from experiments using a suite of synthetic data sets demonstrate that the behaviour of M-Elo is consistent with expectations and outperforms the standard Elo-based model (Elo) in parameter settings that better reflect real-world environments. The results from experiments on multiple benchmarking public data sets indicate that M-Elo has slightly superior predictive performance compared to Elo. Conducting a case study suggested that using M-Elo in adaptive learning systems has additional advantages beyond using Elo. The first advantage lies in the ability of the model in estimating concept-level competencies which can be used for guiding adaptivity. The second advantage lies in the ability of M-Elo to be opened based on the principles of OLMs. Making M-Elo accessible to students increases their motivation to use the platform and increases their trust in the recommendations provided by the platform. It also provides additional insight for instructors on individual student-level or class-level gaps and competencies that can be used to improve item and course design. The conducted case study gave additional insights into the adverse effects of the zero-sum game design of the Elo-based models as well as using an uncertainty functions in the context of adaptive learning. Future work aims to investigate possible extensions of Elo-based models using these considerations and evaluate their fit for adaptive learning systems. In addition, quantitative comparison of M-Elo and traditional models of learner models such as AFM and BKT is required to determine its competitiveness with traditional models in predicting students' performance.

ABSTRACT

We analyze teachers' written feedback to students in an online learning environment, specifically a setting in which high school students in Uruguay are learning English as a foreign language. How complex should teachers' feedback be? Should it be adapted to each student's English proficiency level? How does teacher feedback affect the probability of engaging the student in a conversation? To explore these questions, we conducted both parametric (multilevel modeling) and non-parametric (bootstrapping) analyses of 27,627 messages exchanged between 35 teachers and 1074 students in 2017 and 2018. Our results suggest: (1) Teachers should adapt their feedback complexity to their students' English proficiency level. Students who receive feedback that is too complex or too basic for their level post 13-15% fewer comments than those who receive adapted feedback. (2) Feedback that includes a question is associated with higher odds-ratio (17.5-19) of engaging the student in conversation. (3) For students with low English proficiency, slow turnaround (feedback after 1 week) reduces this odds ratio by 0.7. These results have potential implications for online platforms offering foreign language learning services, in which it is crucial to give the best possible learning experience while judiciously allocating teachers' time.

1. INTRODUCTION

For decades, teacher feedback has been shown to be one of the greatest drivers of student learning [9]. The research focus has shifted from assessing whether feedback is effective to identifying the most powerful strategies [20]. Because of the complex nature of the feedback process, the answer to this question remains deeply tied to the particular context in which it happens. One particular learning domain that is growing fast in terms of number of learners and learning platforms (e.g., Duolingo, Babbel, Learning English at Coursera) is online learning of English as a foreign language (EFL). Despite its increasing prominence, teacher feedback

in the online EFL context has received limited research attention [20, 5].

In this paper we seek to contribute to the understanding of how teacher feedback influences students' behavior in the online EFL context. In particular, we focus on an EFL program in which students learn English with the help of a remote teacher (RT), who is a native English speaker, with whom students communicate online using discussion forums. Within this context, we seek to build an understanding of how the feedback the RTs give to their students affects their posting behavior: (1) How complex should the RT feedback be? (2) Should it be somehow adapted to their student's English proficiency level? (3) How does RT feedback affect the probability of engaging the student in a conversation? This research has potential implications for the countless online platforms offering foreign language learning services, aiming to enhance students' learning experience.

Learning environment: This study is conducted in the context of a program for EFL learning created for secondary school students who attend the public school system in Uruguay. Uruguayan secondary school students (native Spanish speakers) often struggle with English, having very disparate proficiency levels when they enter high school. This program, known as Tutorials for Differentiated Learning (TDL), was conceived to help tackle this problem by providing the students with the option to learn and practice English at their own pace. For this purpose, a set of resources and exercises for EFL learning are made available online through an LMS system. The students are encouraged by their classroom English teachers (CT) to explore the material and complete the exercises, but participation in the program is not mandatory. Completing an exercise consists of reading the material and posting a comment in English in a discussion forum. Exercises are organized in topics (e.g., music, sports, fashion, national parks, travel, etc) and there is one discussion forum per exercise. A RT, assigned to each classroom, reviews the students' posts and gives them individualized feedback.

RT-student interactions: The student always starts the thread by posting a comment about a given topic in the LMS discussion forum. The RT replies giving the students personalized feedback on what they wrote. Then, the conversation may or may not continue depending on whether the student posts a new comment on the given thread. If the

Cecilia Aguerrebere, Monica Bulger, Cristóbal Cobo, Sofía García, Gabriela Kaplan and Jacob Whitehill "How Should Online Teachers of English as a Foreign Language (EFL) Write Feedback to Students?" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 234 - 239

student doesn't, that conversation ends there, and the student may start new threads when doing new exercises. Here is an example of an interaction where the student engaged in the conversation:

Student: *I do not have favorite music I like to listen to everything a little.*

RT: *That's great Alicia. What's your favourite song right now?*

Student: *At this moment I've heard a song from Michael Jackson that I loved its name is Thriller.*

RT: *Ok Alicia, thank you for sharing that :)*

and another example where she didn't:

Student: *I see six oceans: Atlantic, Indian, Pacific, Atlantic, Arctic and Southern ocean.*

RT: *Very well Andrea.*

Learning English: In TDL, the RTs' feedback is intended less as a way of correcting students' mistakes and more as a way to encourage students to participate. Participation in the discussion forums is expected to be conducive to better learning since doing the exercises requires *reading* the material in English as well as *writing* the response in English. Therefore, two measures of interest are: the total comments the student posts and whether the student engages in a given conversation with the RT.

2. PREVIOUS WORK

Even though there is no unified definition of feedback, the seminal work by Hattie and Timperley [9] conceptualizes feedback as *information provided by an agent regarding aspects of a student's performance or understanding*. It can be provided effectively, but it is dependent on several factors such as the task, the learning context and the learners [9, 20]. It may improve learning outcomes when it has a direct use (e.g. correct the task), or it may increase motivation when only expressing praise for the student [20].

In the online language learning context, feedback has been reported as a fundamental aspect in skills development [11]. Teacher feedback in online language learning environments can also inform development of data-driven personalized feedback. Emerging data-driven learning systems adapt feedback to individual student needs, and have been shown to improve learning outcomes [17]. Furthermore, data mining has been used to understand the effects that polarity (positive vs. negative comments) and timing can have in different student's learning aspects [12, 16].

Research on feedback for EFL learning in computer-mediated (CM) environments has widely focused on *peer* feedback, often on EFL writing [18]. Jiang and Ribeiro [10] present a systematic literature review on the effect of CM peer written feedback on adult EFL writing. They confirmed the findings from previous research acknowledging the positive impact of CM peer feedback in this context.

As in many other subjects in educational data mining, most research on feedback has focused on higher education settings [20], leaving the fundamental need to build understanding of the primary and secondary education contexts unattended. We find previous work on secondary and primary education contexts on particular topics such as teachers' feedback strategies [3], student-generated feedback [8] among other more general examples [15].

Figure 1: Histogram of the total comments posted by each student (top left). Histograms of the average complexity (top right), specificity (bottom left) and polarity (bottom right) of the RTs' feedback (red) and of the students' posts (violet).

Our work complements and enriches the previous work in several aspects: (1) it studies asynchronous teacher feedback in an online EFL environment, which has been seldom studied [19], (2) it considers a secondary education setting, also fundamental and rarely analyzed [20], (3) it follows a quantitative analysis exploiting a large scale dataset (in terms of number of students, teachers, classrooms, and school diversity) as opposed to most case studies which often include relatively few students or classrooms [19].

3. DATASET DESCRIPTION

The dataset under consideration was originally collected by Aguerrebere et al. [2] and includes all the comments (i.e., content, posting date, user id) as well as administrative information (for each student, who are her CT and RT) for the 1st secondary school classrooms (12-year-olds) that participated in the TDL program during school year 2017. In this work the dataset is extended to also include school year 2018. This includes a total of 27,627 comments exchanged between 1074 students, organized in 83 classrooms (in 49 public high schools located in 18 different states in the country), and 35 RTs. The dataset has a nested structure: students are organized into classrooms. Each classroom has a dedicated classroom teacher; in contrast, each remote teacher may serve multiple classrooms. Figure 1 shows the histogram of the total comments posted by each student during their corresponding school year. The dataset has been de-identified to preserve each participant's privacy and handled according to Uruguayan privacy protection legislation. After talking with the TDL stakeholders and the program leaders, a set of features characterizing each comment was defined: *complexity*, *specificity*, *polarity* and *response delay*. Each feature represents a different aspect of how elaborate a comment is (*complexity*, *specificity*), its tone (*polarity*) and how long the student had to wait to receive feedback (*response delay*).

Complexity (c) measures how elaborated a comment is, by adding its characters per word, words per sentence and total sentences: $c = \frac{1}{4} \frac{\#char}{\#words} + \frac{1}{5} \frac{\#words}{\#sent} + \#sent$ (weights are included to give similar relevance to all terms, 4 and 5 are the median characters per word and words per sentence respectively). Examples of low, medium and high complexity com-

ments are: ($c = 2.4$) “*Well done!*”, ($c = 3.7$) “*My favourite national park is Yellowstone.*”, ($c = 8.9$) “*Hi Alberto! This is an accurate description of the different continents, but can you try again? The activity is asking about different volcanic landforms! Can you please look at the encyclopedia and read the part about volcanic landforms to find the names of the three types of volcanic landforms? Here’s the link: [link]*”.

Specificity (s) measures how specific, on average, the words are in the comment. It combines how deep each word w_i appears in the WordNet [13] structure and how frequent the word is in the dataset: $s = \frac{1}{W} \sum_{i=1}^W \frac{\text{depth}(w_i)}{Z} + \frac{1}{\text{freq}(w_i)}$, where W is the total words in the comment and Z a normalizing factor equal to the maximum average comment complexity [6]. Examples of comments with low and high specificity: ($s = 0.1$) “*Very good! Do you have any cats?*” and ($s = 1.2$) “*The skeleton of brontosaurus.*”.

Polarity (p) measures the tone of the comment (positive, negative) as the average of an index (-1 (negative) to +1 (positive))¹ assigned to each sentence based on the adjectives it contains (e.g., great, nice, awful). Examples of positive and negative comments: ($p = 1.0$) “*Great Carla! Awesome spelling!*” and ($p = -0.6$) “*I would not like because they are dangerous.*”.

Response delay (τ) is the timelapse between the student’s post and the RT’s response in days. Median τ is 3 days.

Figure 1 shows the histograms of the the average *complexity*, *specificity* and *polarity* of the RTs’ feedback and the students’ posts. The average specificity tends to be larger for students than for RTs; this is likely because students’ comments are responses to exercises that elicit very specific words such as “*skeleton of brontosaurus.*”, whereas the RTs’ comments often contain basic words, e.g., “*Great work!*”.

4. DATA ANALYSIS

We examine the effects of various feedback characteristics of RTs’ feedback on students’ posting behavior. We use two complementary approaches [14]: (1) multilevel linear regression that models the nested nature of the data; and (2) non-parametric bootstrap analysis. The latter is more complicated (e.g., requires a bin width parameter) but can model non-linear relationships and makes fewer assumptions (e.g., normality of residuals) than many parametric models.

4.1 How complex should the RT feedback be?

In this section we are interested in the question: Does RT feedback complexity (low vs. high) affect the total number of comments posted by the student? Note that we must consider the potential confound of the student’s English proficiency level, as the effect of RT feedback complexity may vary for more or less proficient students.

4.1.1 Non-parametric approach

To answer this question we first follow a non-parametric approach, using bootstrap to test the null hypothesis:

$$H_0: E[T|S_c] = E[T|S_c, R_c], \quad (1)$$

¹The *sentiment* function of the PATTERN.EN Python module was used: www.clips.uantwerpen.be/pages/pattern-en.

versus $E[T|S_c] \neq E[T|S_c, R_c]$, where T is the total comments posted by the student, S_c is the student’s English proficiency level (low/high) and R_c is the complexity level of the feedback the student received from his RT (low/high). Hypothesis (1) tests whether the total comments posted by the student depend on the complexity level of the feedback she received from her RT, after conditioning on her English proficiency level. If the null hypothesis is rejected, then the complexity level of the feedback that the students receive affects their average engagement with the program, measured by the total comments they post and conditioned on their English proficiency level. It is important to note that we must reject the null hypothesis if $E[T|S_c]$ differs statistically significantly from $E[T|S_c, R_c]$ for *any* values of S_c and R_c . For this reason, in this section we examine the potential impact of R_c on T for each possible combination of (S_c, R_c) .

To estimate the student’s English proficiency level we use the average complexity of the comments posted by the student. Students with average complexity below (above) the median are classified as having low (high) proficiency respectively. Similarly, the complexity level of the RT’s feedback is low (high) when it is below (above) the median.

Bootstrapping for equality of means: How can we test whether $P(T|S_c, R_c = \text{low})$ and $P(T|S_c, R_c = \text{high})$ have the same mean? If the distribution $P(T|S_c, R_c)$ were Gaussian for all values of S_c and R_c , then we could just use a t-test to compute the p -value (or a nested ANOVA to take into account the nested structure of the data). However, in our case the data are not Gaussian (see [1]). Fortunately, the bootstrap procedure proposed by Efron & Tibshirani [7] provides a rigorous methodology. By sampling *with replacement* from our original dataset, we can *simulate* multiple data samples. We subselect the data for which $R_c = \text{low}$ and the data for which $R_c = \text{high}$ and then resample each of them to generate multiple bootstrap samples. To enforce the null hypothesis (i.e., equal means), we *set* the means of the two samples to be equal to the mean of the combined sample. We then compute the normalized difference in means between the two subsets in the bootstrapped sample. Over all B bootstrap iterations ($B = 10000$), we finally compute the fraction in which the normalized difference in means is at least as large as the observed statistic. See [1] for a detailed description of the algorithms.

Results: For high level students, more *basic* feedback is associated with more posting. Students who received high level feedback posted on average 22% fewer comments than those who received low level feedback (9.3 versus 12 total comments, $p = 0.006$). Examples:

Student A: *My favorite food is hamburger.*

RT (low level): *Nice Lucia! What do you eat in your hamburger?*

Student B: *They are in Spain in Barcelona.*

RT (high level): *Hello Pablo! Yes they are in Spain. Very good. Here is a link in case you would like to know a bit more about Spain and their culture. In Uruguay there are a lot of people who have Spanish origins. It is very evident in the food :) I have never been to Spain. Would you like to go to Spain?*

A possible explanation for this behavior is that even the *high-level* students have weak English proficiency and might feel overwhelmed by feedback that is too complex. No statis-

tically significant differences are observed for low level students (8.5 versus 7.6 total comments, $p = 0.14$).

4.1.2 Controlling for the RT

Another possible confound is the effect of the RT, as more motivated RTs may give better feedback that leads to more posts by their students. To take this into account, null Hypothesis (1) is reformulated as:

$$H_0 : E[T|S_c, RT] = E[T|S_c, R_c, RT], \quad (2)$$

versus $E[T|S_c, RT] \neq E[T|S_c, R_c, RT]$, where RT is the student's remote teacher. If Hypothesis (2) is rejected, the complexity level of the feedback *a given RT* gives to his students has an effect on the total comments posted by them. A variation of the bootstrapping algorithm is used to test Hypothesis (2) where, instead of defining the *[low, high]* RT feedback complexity levels globally from all samples, independent thresholds are defined for each RT.

Results: The result previously obtained remains valid even when conditioning on the RT (i.e., resampling within each RT), meaning that different feedback levels given by the RT to his students are associated with different total posts (8.9 versus 12.5 total comments, $p = 0.01$). No statistically significant differences are observed for low level students.

Even if controlling for the RT makes the result more *solid* from a statistical point of view, interpreting the results becomes more difficult, as the meaning of *low* and *high* complexity feedback changes from RT to RT. Because a fundamental goal is to translate these results into useful information for the teachers, this approach has the disadvantage that an *absolute* complexity level reference cannot be given to them as reference of what *low* and *high* means, and how to position the feedback they give with respect to that.

4.1.3 Parametric Approach

A parametric approach is conducted to complement the results obtained by the non-parametric analysis, allowing for the inclusion of additional predictors (possible confounds) and avoiding binning (in RT complexity). Binning is kept to determine student level (low/high), as separate models are computed for each case. In order to take into account the nested structure of the data, a multilevel modeling approach is employed where the CT and RT effects on the student's activity are modeled as nested random effects. Therefore, we model student i 's total posts as a negative binomial random variable, to account for the fact that it is count data with overdispersion, with expected value μ_i given by:

$$\log(\mu_i) = \beta + \gamma_0 c_i + \gamma_1 y_i + \gamma_2 p_i + \gamma_3 s_i + \gamma_4 \tau_i + C + R, \quad (3)$$

(capital letters denote random variables and lower-case denote fixed values). β is the baseline total comments. c_i , p_i , s_i and τ_i are the average complexity, polarity, word specificity and response delay of the feedback comments student i received from his RT, respectively. y_i is the school year. The fixed effects $\gamma_0, \dots, \gamma_4$ represent the effects of the corresponding covariates on the total comments. The nested random effect CT-RT is represented by the random variables C and R , assumed to follow zero-mean Gaussian distributions with standard deviations σ_C and σ_R . All the parametric models were fit using the R *lme4* package [4].

	stud. level	β	$\hat{\gamma}_0$	$\hat{\gamma}_1$	$\hat{\gamma}_2$	$\hat{\gamma}_3$	$\hat{\gamma}_4$
Model 3	low	1.12 **	0.03	0.30 .	-0.03	0.76	0.01
	high	2.50 ***	-0.11 *	0.26	-0.02	-0.02	0.04
Model 4	low	1.63 ***	-0.14 **	0.25	-0.32	0.67	-0.01
	high	2.24 ***	-0.16 **	0.22	-0.06	0.12	-0.002

Table 1: Effects of RT feedback on students' total comments for Models 3 and 4, in log scale. Signif. codes: 0 (*) 0.001 (**) 0.01 (*) 0.05 (.) 0.1**

Results: Table 1 (Model 3) shows the computed effects for all the covariates. The parametric analysis, which includes other possible confounds, confirms the same tendency observed with the non-parametric approach: a negative statistically significant effect of the RT feedback complexity level is observed for high level students ($\exp(-0.11) = 0.9$, i.e., 10% less total posts per unit increase in RT average complexity) and no effect is observed for low level students. To compare this result to the one obtained by the non-parametric approach, we compute the equivalent per unit decrease in the non-parametric case (computed as the total decrease divided by the difference between the average RT complexity in the two compared levels, 3.8 and 5.9) which equals 10%.

4.2 Should RTs feedback complexity be close to that of their students?

Rather than the *absolute* complexity, we can also consider the *relative* complexity of the RTs' feedback compared to the complexity of students' comments. Put another way: should the feedback complexity be somehow *adapted* to the student? To answer this question we propose to model the total comments posted by the student as a function of the *distance* between the average complexity of the student's comments and the average complexity of the feedback the student received from his RT.

4.2.1 Parametric approach

We model each student i 's total posts as a negative binomial random variable with expected value μ_i given by:

$$\log(\mu_i) = \beta + \gamma_0 |c_i - c_{s_i} - \alpha| + \gamma_1 y_i + \gamma_2 p_i + \gamma_3 s_i + \gamma_4 \tau_i + C + R, \quad (4)$$

The fixed effect γ_0 represents the effect of the absolute value of the difference between the student's (c_{s_i}) and the RT's (c_i) average comments complexity, where α is introduced as an offset to account for the fact that the feedback may need to be close to that of the student but not necessarily equal. See Model 3 for the definition of the rest of the variables.

Setting α : Model 4 is fitted for different values of α and the one corresponding to the largest log-likelihood is selected. For low student levels the maximum log-likelihood is obtained at $\alpha = 0.25$, whereas for high student level it is at $\alpha = -0.79$. Hence, this analysis suggests that even if for both low and high level students feedback complexity should be close to the student level, low level students benefit from feedback slightly more complex than theirs whereas high level students benefit from feedback slightly below theirs. Recall that low level students post very basic comments, whereas those of high level students tend to be more elaborated but remain still simple.

Results: Table 1 (Model 4) shows the computed fixed effects for the different covariates. The distance between the average complexity of the student's comments and the average complexity of the feedback the student received from his RT has a negative stat. sig. effect on the total comments posted by the student. There is a 13% ($p = 0.008$) and 15% ($p = 0.003$) decrease in total comments with one unit distance increase, for the low and high level students respectively. We present in the following a series of examples in order to help the reader gain insight into what small and large student-RT complexity distance mean in practice.

Large distance:

Student A: *I would like to defile.*

RT: *Nice try Marcela, but I do not understand what you mean. There are two models in the above photo, can you tell me which model is from Brazil and which model is from the USA? or - can you tell me, who is your favourite model? My favourite model is Kate Moss.*

Small distance:

Student A: *My favorite sport is football.*

RT: *Very good! what is your favorite football team?*

In the latter example, the interactions seem closer to an online chat for students with basic English skills.

4.2.2 Non-parametric approach

A non-parametric approach is conducted to complement the results obtained by the parametric analysis. For this purpose, bootstrapping is used to test the null hypothesis:

$$H_0 : E[T|S_c] = E[T|S_c, D], \quad (5)$$

versus $E[T|S_c] \neq E[T|S_c, D]$, where D is the distance between the student's and the RT's average comments complexity as defined in Model 4. The bootstrapping algorithm introduced in Section 4.1.1 is used, with a for loop on small and large D (below and above the median distance) instead of RT complexity, and α is set to the values obtained in Section 4.2.1 (see [1] for details).

Results: A negative statistically significant effect is observed for D on the total comments posted by the student, both for low and high level students. Students who received feedback less adapted to their level posted 15% and 34% less comments than those who received more adapted feedback, for low (6.6 versus 7.6 total comments, $p = 0.007$) and high (9.2 versus 12.3 total comments, $p < 0.001$) level students respectively. To compare these results to those obtained by the parametric approach we compute the equivalent per unit decrease (computed as the total decrease divided by the difference between the average D in the two compared levels) which equals 9% both for low and high student level.

4.3 Engaging students in conversation

The program aims at motivating the students to interact with others in English. Therefore, we are interested not only in their total posts but also in the probability of engaging them in a conversation. Following the same rationale as Section 4.1.3, we use a multilevel logistic regression model to explore this question. Let $(Y_j)_{j=1,\dots,N}$ be Bernoulli variables with $P(Y_j = 1|\eta_j) = \exp(\eta_j)/(1 + \exp(\eta_j))$ with:

$$\eta_j = \beta + \gamma_0 c_j + \gamma_1 \log(\tau_j) + \gamma_2 p_j + \gamma_3 s_j + \gamma_4 y_j + \gamma_5 q_j + \gamma_6 l_j + \gamma_7 e_j + S + C + R, \quad (6)$$

$Y_j = 1$ if the student posts a second comment in conversation j and 0 otherwise. β is the baseline. c_j , p_j and s_j are the complexity, polarity and specificity of the RT's response to the first comment posted by the student who initiated conversation j . q_j , e_j and l_j are boolean variables taking value 1 if the RT's response asked the student a question, included an emoticon or shared a link respectively. τ_j is the timelapse between the moment the student started conversation j and the RT replied. y_j is the school year. $\gamma_0, \dots, \gamma_7$ represent the fixed effects of the corresponding covariates. The nested random effect student-CT-RT is represented by the random variables S , C and R , assumed to follow zero-mean Gaussian distributions with standard deviations σ_S , σ_C and σ_R . N is the total number of conversation threads and there may be several threads per student.

Results: Table 2 shows the estimated covariate effects. By far, and maybe not surprisingly, the fact that the RT asks the student a question has the largest stat. sig. positive effect on the probability of getting the student to continue the conversation. When a question is asked, assuming the rest of the covariates remain fixed, the odds ratio for students of the same classroom is $\exp(2.94) = 19.0$ and $\exp(2.86) = 17.5$, for low and high level students respectively.

As more elaborated comments often include questions, the positive effect of complexity suggests that more elaborated comments increase the probability of engaging a student in a conversation. On the contrary, the negative stat. sig. effect of polarity is likely due to the fact that very positive comments such as "Great work!" tend to be quite basic in terms of complexity. For high level students a larger delay is associated with more responses, as after a one week delay the odds ratio is 1.2 (the rest of the covariates and random effects remaining constant). This is likely because for high level students RT response delay is positively correlated with complexity (Spearman 0.1) and negatively correlated with comments polarity (Spearman -0.12): writing more elaborated comments take longer. This is not observed for low level students (Spearman 0.02 for both complexity and polarity), for whom it seems important to reply as soon as possible, as after a one week delay the odds ratio is 0.7. Finally, for both high and low level students, results suggest that using less specific words is associated with higher probability of engagement in the conversation.

5. SUMMARY AND CONCLUSIONS

We conducted an observational analysis of 27,627 comments, exchanged between 1074 high school students and 35 RTs over 2 years, to study the effect that different RT's feedback characteristics have on the students' posting behavior in an online EFL learning environment. The research questions, as well as the features defined for the characterization of the comments, were discussed and validated with the stakeholders and the leaders of the program in order to take advantage of their wide experience on the topic. Both parametric (multilevel modeling) and non-parametric (bootstrapping) analyses were performed, controlling for the effect of possible confounds such as (1) the classroom teacher, (2) the remote teacher and (3) the students' English proficiency level. Our results suggest that:

(1) Teachers should observe the complexity of their students' comments and adapt the complexity of their feedback ac-

student level	β	$\hat{\gamma}_0$	$\hat{\gamma}_1$	$\hat{\gamma}_2$	$\hat{\gamma}_3$	$\hat{\gamma}_4$	$\hat{\gamma}_5$	$\hat{\gamma}_6$	$\hat{\gamma}_7$
low	-7.11 ***	0.08	-0.15 ***	0.36 ***	-2.20 **	0.24	2.94 ***	-0.53	0.11
high	-7.46 ***	0.35 ***	0.10 **	-0.47 *	-2.66 **	0.62	2.83 ***	-0.77	-0.39

Table 2: Effects of RT feedback characteristics on the probability of engaging the student in conversation, in logarithmic scale. Significance codes: 0 (*) 0.001 (**) 0.01 (*) 0.05 (.) 0.1**

cordingly. Students who receive feedback that is too complex or too basic for their level post 13% ($p = 0.008$) and 15% ($p = 0.003$) fewer comments than those who receive adapted feedback, for low and high level students respectively.

(2) According to some RTs who were consulted about the potential causes of the observed behavior, the students may be more motivated when the language of the RT is accessible to them because they understand it, they learn from it and are challenged by it, without this turning into frustration.

(3) The best way to engage the students in a conversation is to pose a question (this increases the odds by 19 and 17.5 for low and high level students respectively). The comments should be complex enough to include a question (i.e., “Great work!” won’t be enough) yet remain simple in terms words specificity. Also, for low level students, it is important to respond as quickly as possible (after a one week delay the odds ratio is 0.7).

Even if no causal inferences can be made, this study generated enlightening insights which have potential implications for the countless online platforms offering foreign language learning services, in which it is crucial to give the best possible learning experience while judiciously allocating resources (e.g. teachers’ time).

Acknowledgments: We thank the TDL team and RTs for their participation and helpful feedback. J. Whitehill was supported by the National Science Foundation under Grant No. #1822830.

ABSTRACT

Personalized education systems recommend learning contents to students based on their capacity to accelerate their learning. This paper proposes a personalized exercise recommendation system for online self-directed learning. We first improve the performance of knowledge tracing models. Existing deep knowledge tracing models, such as Dynamic Key-Value Memory Network (DKVMN), ignore exercises' concept tags, which are usually available in tutoring systems. We modify DKVMN to design its memory structure based on the course's concept list, and explicitly consider the exercise-concept mapping relationship during students' knowledge tracing. We evaluated the model on the 5th grade students' math exercising dataset in TAL, one of the biggest education groups in China, and found that our model has higher performance than existing models. We also enhance the DKVMN model to support more input features and obtain higher performance. Second, we use the model to build a student simulator, and use it to train an exercise recommendation policy with deep reinforcement learning. Experimental results show that our policy achieves better performance than existing heuristic policy in terms of maximizing the students' knowledge level. To the best of our knowledge, this is the first time that deep reinforcement learning has been applied to personalized mathematic exercise recommendation.

1. INTRODUCTION

Online self-directed learning systems, such as Massive Open Online Courses (MOOCs), are prevailing. These systems, however, assign same exercises to all students, which is inefficient. For comparison, personalized exercises recommendation can improve the efficiency of students' learning. In

this paper, we propose a personalized exercise recommendation system for an online self-directed learning service. The system consists of two parts:

- A student knowledge tracing model, which traces a student's knowledge state and predicts whether or not she can finish the exercise correctly.
- A personalized exercise recommendation policy which recommends appropriate exercises to students to accelerate her learning process.

Existing deep knowledge tracing models [9, 13] ignore exercises' knowledge concept properties, which are usually available in tutoring systems. For comparison, in this paper, we propose a concept-aware deep knowledge tracing model. The model is inspired by Dynamic Key-Value Memory Network (DKVMN) model [13]. DKVMN model has a static matrix called *key* which stores the latent knowledge concepts and a dynamic matrix called *value* which stores a student's concept mastery levels. The model computes the correlation between an exercise and the latent concepts in the *key*, and then uses it to read the student's concept mastery levels in the *value*, and predict whether the student will finish the exercise correctly. We improve the DKVMN model as follows: 1) we design its memory structure based on the course's concept list and explicitly consider the exercise-concept mapping relationship during students' knowledge tracing. 2) We enhance it to support more input features, including exercise difficulty, stages, and student practice time. We evaluated the model on the 5th grade students' math exercising dataset in TAL, and found that our model has higher performance than existing deep knowledge tracing models.

In terms of personalized exercise recommendation policy, most of existing algorithms are heuristic, e.g., exercises which are too easy or too hard for a student should be avoided. These algorithms may be not optimal, as they only consider the short-term reward. In this paper, we build a student simulator with our concept-aware deep knowledge tracing model, and then use it to train a flexible and scalable personalized exercise recommendation policy with deep re-

Fangzhe Ai, Yishuai Chen, Yuchun Guo, Yongxiang Zhao, Zhenzhu Wang, Guowei Fu and Guangyan Wang "Concept-Aware Deep Knowledge Tracing and Exercise Recommendation in an Online Learning System" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 240 - 245

inforcement learning, which considers long-term reward of recommended items.

In summary, the main contributions of this paper are two folds:

- We propose a new exercise-level deep knowledge tracing model whose structure is built based on the course's concept list, and the exercise-concept mapping relationships are utilized during students' knowledge tracing. The model supports more input features and obtains higher performance compared with existing models.
- We propose an exercises recommendation algorithm which uses model-free reinforcement learning with neural network function approximation to learn an exercise recommendation policy. The policy directly operates on raw observations of a student's exercise history. Experimental results show that our policy achieves better performance than existing heuristic policy in terms of maximizing students' knowledge level.

2. RELATED WORK

Knowledge Tracing: The work in [3] proposed a Bayesian-based knowledge tracing model. It models a student's status of a knowledge concept as a binary variable, and updates the probability of her mastering the concept according to her results of doing exercises through a Hidden Markov Model. This model is at the concept level, and ignores the relationship between different concepts. The work in [9] proposed a deep knowledge tracing (DKT) model with recurrent neural network. It models a student's knowledge states as latent variables, and gets better performance than Bayesian-based model does [6]. The work in [12] proposed to improve DKT by considering exercises' semantic features. The work in [13] tried to model the correlation between different latent concepts. Inspired by DKVMN, this paper proposes a model whose structure is explicitly built based on the course's concept list, and the exercise-concept mapping relationship is utilized in the model.

Exercise Recommendation: The work in [1] proposed that a student is recommended by an exercise, if the probability of her doing the exercise correctly is around 50%. The problem of this algorithm is that the threshold 50% is heuristic and may be not optimal. The work in [2] allows experts to specify a ZPD (Zone of Proximal Development) based on current knowledge state of a student, and then chooses the most profitable exercise by multi-armed bandits algorithm. The algorithm can discover the characteristics of students through exploration but it is inefficient, because every student needs an independent exploration process. The work in [5] leverages a DKT model towards recommendation, and frame the problem space using ZPD explicitly facilitated by the DKT model. The work in [7] first estimates each student's knowledge profile from their previous exercise results using SPARFA framework. Then, it uses these knowledge profiles as contexts and applies contextual bandits algorithm to recommend exercises, for maximizing a student's immediate success, i.e., her performance on the next exercise. The problem of this algorithm is that it only considers the next step and thus its performance may be

not optimal. The work in [10] evaluated a review scheduling algorithm for spaced repetition systems based on deep reinforcement learning. We are inspired by this work and evaluate the performance of deep reinforcement learning in our math self-directed learning system.

3. BACKGROUND

In this section, we introduce our online learning system and dataset.

3.1 Intelligent Practice System (IPS)

IPS is an online self-directed learning system developed by TAL Education Group, Inc. of China. In IPS, each course (e.g., the 5th grade math) has tens of units. Each unit includes 7 stages, i.e., 1) warming-up exercises before class, 2) in-class exercises before lecture, 3) video lecture, 4) in-class exercises after lecture, 5) homework exercises, 6) unit review exercises, 7) multi-units review exercises. In these 7 stages, stages 1, 2, 3, 4, 5 include contents of a single knowledge concept, but stages 6 and 7 include exercises of other knowledge concepts in order to review. As IPS is a self-directed learning system, a student can choose any teaching unit to study. In a unit, she can also exit current stage or the whole unit at any time. The system records the student's learning duration in each stage, the exercises she practices, and her results, i.e., whether or not the answer is correct.

In IPS, each exercise has three knowledge concept tags, which are provided by experts. The knowledge concept tags have a hierarchical tree structure. For instance, for one exercise, its 1st, 2nd, and 3rd level concept tags are "Number Theory", "Prime Number and Composite Number", and "Decomposition of Prime Factor", respectively.

3.2 Data Set and Data Pre-Processing

We use a sample of anonymized student usage interactions from the 5th grade math curriculum in IPS. We choose exercising records whose first-level knowledge concept is "Number Theory", which has 7 second-level knowledge concepts and 15 third-level knowledge concepts. We further choose students whose exercise records include at least 5 exercises. The resulting dataset includes 44,128 exercise records of 7,124 students.

4. KNOWLEDGE TRACING MODEL

We now introduce our knowledge tracing model based on DKVMN model, and highlight our improvement in aspects of memory structure, knowledge concept weight, and read and update process.

4.1 Concept-Aware Memory Structure

We modify DKVMN to design its memory structure based on the course's concept list. Fig. 1 plots the model's structure, which is based on DKVMN model [13]. As shown in Fig. 1, \mathbf{M}_t^k is the concept embedding matrix whose size is $M \times N$, where N is the number of memory locations, and M is the vector size at each location. We set N equal to the number of the course's knowledge concepts. As we have 1 first-level knowledge concept, 7 second-level knowledge concepts and 15 third-level knowledge concepts, we have $N = 23$. Then, in each location, the student's state for the corresponding knowledge concept is saved. Thus, the

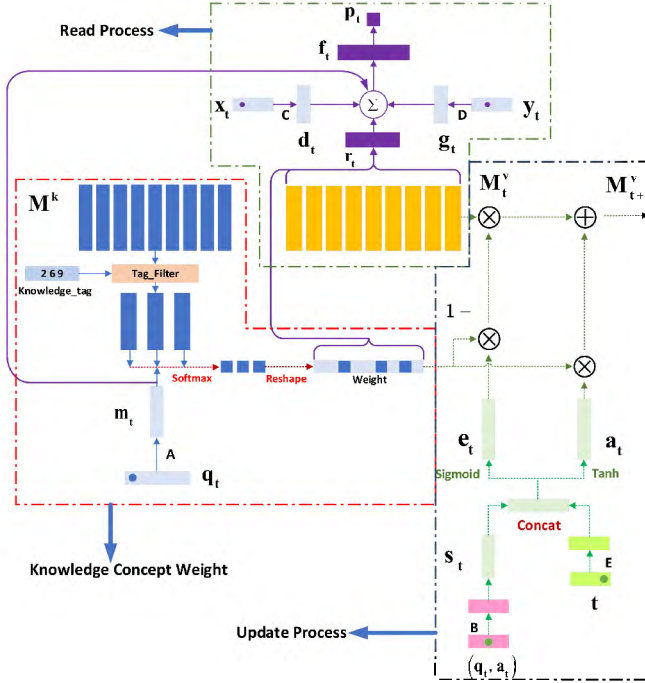

Figure 1: Concept-aware DKVMN model structure.

model's memory architecture is explicitly designed to represent knowledge concepts. For comparison, N is a model parameter in DKVMN representing the number of latent knowledge concepts, e.g., $N = 5$. As our model is inspired by DKVMN, we name it Concept-Aware DKVMN, i.e., *DKVMN-CA*.

4.2 Knowledge Concept Weight

As a student's state of a knowledge concept is saved in the corresponding memory location, when a new exercise arrives, only the exercise's related concepts' memory locations are retrieved and updated. We now present the details of such a procedure. In this section, we calculate the knowledge concept weight (KCW) of the exercise. The weights will be used to calculate the weighted sum of a user's current knowledge concept states to predict her performance on the exercise. It will also be used to update the student's knowledge state after obtaining the answer result of the student on the exercise.

We first obtain the embedding of the arrived exercise. As shown in Fig. 1, when an exercise q_t arrives at time t , it is first transformed into an embedding vector m_t through an exercise embedding matrix A . We then calculate the KCW through Algorithm 1. As shown in Algorithm 1, at line 2, we initialize the weight list R . As each exercise has three knowledge concepts, the length of R is 3. Then, for each knowledge concept k (line 2), we calculate the dot product of the embedding of the exercise (i.e., q_t) and the concept embedding (line 3). We then calculate the KCW by obtaining softmax of R , with $\text{Softmax}(z_i) = e^{z_i} / \sum_{j=1}^N e^{z_j}$ (line 6). Then, we initialize an all-zero vector *Weight* whose length is the number of the knowledge concepts N (line 7). For each knowledge concept k of the exercise (line 8), we set

its weight value in *Weight*.

In summary, DKVMN computes the relationship weights between the exercise and all latent knowledge concepts, but we just compute the relationship weights between the exercise and its knowledge concepts. For the exercise's relationship weights with other concepts, we set them zeros.

Algorithm 1 Knowledge Concept Weight Calculation

Input:
 q_t : embedding of the exercise arrived at time t
 K_t : knowledge concept list of q_t
 M^k : the concept embedding matrix

Output:
Weight: Knowledge concept weight of the exercise arrived at time t

/ Calculate KCW */*

- 1: $R \leftarrow []$
- 2: **for** each $n \in K_t$ **do**
- 3: $corr \leftarrow m_t^T \cdot M^k[n]$
- 4: $R.append(corr)$
- 5: **end for**
- 6: $R_s \leftarrow \text{Softmax}(R)$
- /* Reshape the weight vector to make its length equal to the number of concepts */*
- 7: $Weight \leftarrow [0, \dots, 0]$
- 8: $i \leftarrow 0$
- 9: **for** $i < 3$ **do**
- 10: $Weight[K_t[i]] \leftarrow R_s[i]$
- 11: $i \leftarrow i + 1$
- 12: **end for**
- 13: **return** *Weight*

4.3 Read Process

We then use the obtained KCW to calculate the weighted sum of the user's current knowledge concept states to predict the student's performance on the exercise. Denote KCW by w , we have $r_t = \sum_{i=1}^N w_i M_t^v$, i.e., the knowledge state of concepts related to the exercise q_t .

We further concatenate r_t with the embeddings of the exercise's difficulty and stage feature, i.e., d_t and g_t . The result then passes through a fully connected layer with activation function Tanh to get a summary vector f_t , which contains all information of the student's knowledge state related to q_t and the exercise's features, i.e.,:

$$f_t = \text{Tanh}(W_0^T [r_t, d_t, g_t, m_t])$$

where $\text{Tanh}(z_i) = (e^{z_i} - e^{-z_i}) / (e^{z_i} + e^{-z_i})$.

Finally, f_t passes through a fully connected layer to output the probability that the student would do the exercises q_t correctly. Denote the probability by p , we have

$$p = \text{Sigmoid}(W_1^T f_t)$$

where $\text{Sigmoid}(z_i) = 1 / (1 + e^{-z_i})$.

4.4 Update Process

We then use the KCW to update the student's knowledge state after observing the her answer result. The update process updates the value matrix M_t^v , which represents the student's current state of knowledge concept k . Our model is different from DKVMN model in that we consider the student's exercising duration in the update process. For

comparison, DKVMN ignores this student behavior feature. Specifically, the work in [8] proposed that the a student's duration of solving a problem is related to her master level of latent problem solving skills. Inspired by this work, in our model, after a student finishes an exercise, her answer result (i.e., correct or wrong) \mathbf{a}_t and exercising duration are used to update \mathbf{M}_t^v . Because the exercising duration is a continuous variable, it is firstly discretized according to its distribution and then represented by its embedding \mathbf{t} . We then concatenate \mathbf{t} with the joint embedding \mathbf{s}_t of the answer vector $(\mathbf{q}_t, \mathbf{a}_t)$, to update \mathbf{M}_t^v , as shown in Fig. 1.

The other update process is same as that of DKVMN. It includes erase subprocess and add subprocess. Erase vector is computed as $\mathbf{e} = \text{Sigmoid}(\mathbf{E}^T[\mathbf{s}_t, \mathbf{t}])$, where \mathbf{E} is the erase weights. Add vector is computed as $\mathbf{a} = \text{Tanh}(\mathbf{D}^T[\mathbf{s}_t, \mathbf{t}])$, where \mathbf{D} is the add weights. Then the new memory matrix \mathbf{M}_{t+1}^v is computed by

$$\mathbf{M}_{t+1}^v(i) = \mathbf{M}_t^v(i)[1 - \mathbf{w}(i)\mathbf{e}][1 + \mathbf{w}(i)\mathbf{a}]$$

The parameters of the model are learned by minimizing a standard cross entropy loss between the predicted user answer result p_t and her true result y_t :

$$L = - \sum_t ((y_t \log p_t) + (1 - y_t) \log(1 - p_t))$$

In summary, compared with DKVMN, we design the model structure based on the course's concept list, and then explicitly consider the exercise-concept mapping relationship and other exercise's features during students' knowledge tracing.

5. REINFORCEMENT LEARNING BASED EXERCISES RECOMMENDATION

Based on the DKVMN-CA student knowledge tracing model, we build a student simulator which provides environment for reinforcement learning, and train a personalized exercise recommendation agent with deep reinforcement learning method.

Similar to [10], we model the recommendation process as a Partially Observable Markov Decision Process (POMDP), where the model state is the student's latent knowledge state and the action is the recommendation of an exercise. At time t , the reinforcement learning agent cannot observe the student's latent knowledge state s_t . Instead, it can observe the student's exercise and answer result (i.e., correct or wrong) o_t which is conditioned on the latent knowledge state $p(o_t|s_t)$. Thus, at time t , the agent needs to recommend an exercise a_t based on the student's exercising history before t , which is denoted by h_t . We have $h_t = (o_1, a_1, o_2, a_2, \dots, o_{t-1}, a_{t-1})$. After the student finishes the recommended exercise a_t , her latent knowledge state will turn to s_{t+1} by a transition function $p(s_{t+1}|s_t, a_t)$.

We define the reward r_t of an action a_t as

$$r_t = \frac{1}{K} \sum_{i=1}^K P_{t+1}(q_i), \quad (1)$$

where K is the number of exercises, and $P_{t+1}(q)$ denotes the probability of the student getting exercise q correct after finishing the recommended exercise at state s_{t+1} . It is

predicted by the student simulator. So, we name it as the student's *Predicted Knowledge*.

The purpose of optimization is to maximize the reward R of policy π :

$$R = \mathbb{E}_\pi \left[\sum_{t=1}^{\infty} \gamma^{t-1} r(s_t, a_t) \right],$$

where trajectories $\tau = (s_1, o_1, a_1, s_2, o_2, a_2, \dots)$ are drawn from the trajectory distribution induced by policy $\pi : p(s_1) p(o_1|s_1) \pi(a_1|h_1) p(s_2|s_1, a_1) p(o_2|s_2) \pi(a_2|h_2) \dots$. Thus, as for the action-value function Q^π , the reward of the recommended exercise sequence at t is:

$$Q^\pi(h_t, a_t) = \mathbb{E}_{s_t|h_t} [r_t(s_t, a_t)] + \mathbb{E}_{\tau>t|h_t, a_t} \left[\sum_{i=1}^{\infty} \gamma^i r(s_{t+i}, a_{t+i}) \right]$$

where $\tau > t = (s_{t+1}, o_{t+1}, a_{t+1}, \dots)$ is the future trajectory. The algorithm then recommends the exercise q_t which has the maximal reward, i.e., $q_t = \max_a Q^\pi(h_t, a)$. Similar to [10], we approximately solve the POMDP using Trust Region Policy Optimization (TRPO) algorithm [11], with an off-the-shelf implementation from rllab [4].

6. PERFORMANCE EVALUATION

In this section, we present the performance evaluation results of our system.

6.1 DKVMN-CA Knowledge Tracing Model

We evaluated our model on our IPS dataset. To evaluate it, we conducted 50 experiments. In each experiment, we randomly split the users into two groups: training users and testing users. Their percentages are 70% and 30%. We then trained the model with the training users and evaluated the model on the testing users. Similar to [9], we use area under the curve (AUC) as the performance metric. We report the maximal, mean, and the standard deviation of the testing users' AUCs of all 50 experiments.

6.1.1 Efficiency of Concept-Aware Design

We first report the efficiency of designing the model's architecture based on the course's knowledge concepts. We compare the performance of DKVMN and DKVMN-CA without the help of other input features, including exercise difficulty, stage, and duration. The results are shown in Table. 1. See the rows "DKVMN" and "DKVMN-CA". As shown in Table. 1, our model obtains an AUC of 0.724, which is higher than that of DKVMN model, i.e., AUC = 0.712. Such an improvement is considerable, considering the small improvement DKVMN provides over the DKT baseline (AUC = 0.711). Such a result means that the design of the model's architecture based on the course's knowledge concepts is efficient.

To highlight the necessity of our design, we also evaluate another method which also uses exercises' knowledge concept tags, i.e., represents a knowledge concept by its embedding and then concatenate it with the embedding of the exercise. Its' performance is shown in Table. 1. See the row "DKVMN-KC". As shown in Table 1, its mean AUC is 0.714, meaning a very small improvement over the DKVMN (AUC = 0.712). Thus, it is necessary to design the model's

Table 1: AUC of Models with Different Features

Model	Mean AUC	Max AUC	Variance
LSTM	0.711	0.712	1.86e-05
DKVMN	0.712	0.720	2.05e-05
DKVMN-KC	0.714	0.724	1.85e-05
DKVMN-CA	0.724	0.731	2.14e-05
DKVMN-CA + Stage	0.728	0.736	1.48e-05
DKVMN-CA + Duration	0.725	0.737	1.75e-05
DKVMN-CA + Difficulty	0.726	0.736	2.44e-05
DKVMN-CA + Stage, Duration	0.726	0.739	2.43e-05

architecture based on the course’s knowledge concepts to fully utilize their capacity to improve the model.

6.1.2 Efficiency of Other Exercise Features

We then evaluate the efficiency of adding other features, including exercise difficulty, stage, and duration. The results are shown in Table 1. See the rows "DKVMN-CA + Difficulty", "DKVMN-CA + Stage", and "DKVMN-CA + Duration". As shown in Table 1, these features can further improve the model’s performance. For example, the mean AUC of "DKVMN-CA + Stage" is 0.728, which is higher than that of DKVMN model (AUC = 0.712).

6.2 Exercises Recommendation

6.2.1 Evaluation of Students’ Knowledge Growth Process

We use the Expectimax algorithm proposed in [9] as the baseline algorithm. In the Expectimax algorithm, the system first calculates a student’s predicted knowledge assuming an exercise is recommended to the user to practice. It then chooses the exercise with the highest predicted knowledge to recommend.

To compare the two algorithms, we first randomly pick 15 students in our dataset. For each student, we conduct two experiments, one experiment for one algorithm. In each experiment, we first initialize the student simulator using the student’s historical practice sequence. Then, we continuously recommend 50 exercises to the student simulator with the recommendation algorithm. During the process, we record the average of the 15 students’ predicted knowledge as Eq.(1) at each step of recommendation. The results are shown in Fig. 2. As shown in Fig. 2, the students served by RL policy has a higher mean predicted knowledge than the students served by the Expectimax policy after 50 exercises. Moreover, after about 10 exercises, the mean predicted knowledge of the students served by the Expectimax policy stops increasing, meaning that the policy cannot find exercises which can help the students to improve the performance any more. For comparison, served by the RL policy which considers long-term reward of action, the students’ mean predicted knowledge keeps increasing, meaning that the RL policy still can find exercises which can help the student to improve performance.

**Figure 2: Performance evaluation results****Figure 3: Knowledge State Variation**

6.2.2 Evaluation of Recommendation Process

We design another experiment to observe the recommendation behavior of the RL policy. We randomly pick a student who has practiced five exercises, and use her exercise sequence to initialize the student simulator. Then, we serve her with five more exercises using the RL recommendation policy. Fig. 3 shows the results. The x label of Fig. 3 shows the 10 exercises’ IDs, concepts, and results. For example, the first record (88, 5, 0) means that the exercise ID is 88, which is related to concept 5, and the student’s answer is wrong. As the 10 exercises are related to 6 concepts, we plot the student’s predicted knowledge of each concept in Fig. 3. For instance, as the student fails in the first exercise 88, which is related to the 5th concept, the student’s knowledge status on the 5th concept is relatively low. The status of the knowledge concepts not covered by the student’s history exercises are indicated in black. We now observe the recommended exercises. We have the following observations:

- As shown in Fig. 3, the first five exercises are related to concepts 2,4,5, and the later five exercises are related to concepts 1,3,6, suggesting the RL algorithm wants to explore the student’s capacity in other concepts.

- After the student succeeds in exercise 760, which is related to the concept 3 (Decomposition of Prime Factor), the algorithm recommends the exercise 642, which is related to concept 6 (Maximum common factor and Least common multiple). As concept 6 is related to concept 3, such a recommendation is reasonable.
- The student, however, fails to finish the exercise 642. Thus, the algorithm recommends exercise 642 again. This time, the student succeeds to finish it, meaning that the model captures the phenomenon during training that a student who failed in exercise 642 may succeed if she retries. Such a result is interesting.
- After the student succeeds in exercise 642, which is related to concept 6 (Maximum common factor and Least common multiple), the model's estimation of the student's capacity on concept 3 (Decomposition of Prime Factor) also slightly increases. As these two concepts are indeed related, such a result is reasonable.
- Then, the algorithm turns to another concept again, i.e., it recommends the exercise 1278, which is related to concept 1. While the student succeeds in the exercises, the estimated student's knowledge status on the concept 1, however, is relatively low, suggesting that the exercise is relative easy.
- At last, the exercise 760 is recommended again, and the student succeeds in it. As a result, the model's estimation of the student's capacity on concept 3 increases, suggesting that reviewing is beneficial for study.

7. CONCLUSION

In this paper, we improve DKVMN by designing its neural network structure based on a course's concept list, and explicitly considering the exercise-concept mapping relationship during students' knowledge tracing. We also enhance the DKVMN model to consider more input features. Experimental results show that our model has higher performance than existing deep knowledge tracing models. We also propose an exercises recommendation algorithm which uses model-free reinforcement learning with neural network function approximation to learn an exercise recommendation policy that directly operates on raw observations of a student's exercise history. Our experimental results demonstrate that our policy achieves better performance than existing heuristic policy in terms of maximizing the students' knowledge level. To the best of our knowledge, this is the first time that deep reinforcement learning has been applied to personalized mathematic exercise recommendation.

ABSTRACT

In this paper, we applied a number of clustering algorithms on pre-test data collected from 264 high-school students. Students took the pre-test at the beginning of a 5-week experiment in which they interacted with an intelligent tutoring system. The primary goal of this work is to identify clusters of students exhibiting similar knowledge patterns. In particular, we show that the DP-means clustering algorithm yields very good results using binary response data. Other clustering algorithms such as k-modes have demonstrated better results when using categorical response data.

Keywords

Clustering, intelligent tutoring systems, students modelling.

1. INTRODUCTION

Assessment is a key element in education in general and in Intelligent Tutoring Systems (ITSs) in particular because fully adaptive tutoring presupposes accurate assessment [2, 12].

Capturing students' knowledge state, our focus, and other learner characteristics that are important for learning such as their emotional state is critical to facilitate learning through adaptivity, i.e., tailoring instruction to each individual learner [11]. It should be noted that adaptivity can be thought of at two levels: macro-adaptivity which means selecting appropriate instructional tasks and micro-adaptivity which implies offering appropriate scaffolding while students work on a task (also called within-task adaptivity). Our work presented here could inform both micro- and macro-adaptivity. For instance, understanding the knowledge gaps of students in a particular cluster could inform what instructional tasks to choose for these students, i.e., it informs macro-adaptivity.

Indeed, an important preliminary step in creating an ITS that is sensitive to student misconceptions and individual learning trajectories is to first understand the various levels of mastery with respect to a target domain, for instance, physics. For example, important questions that need to be answered are: What are the predominant misconceptions they hold? and Are these misconceptions evenly distributed across topics and level of course taught? Using the clustering method proposed here will help

answer such important questions. To this end, in this paper, we document for each group of students identified by our clustering algorithm, the major misconceptions exhibited by that group.

In this study, we applied clustering on a pretest data collected at the beginning of an experiment in which high-school students interacted with a dialogue-based ITS. Our goal was to identify student groups and analyze them as a group in terms of misconceptions and mastered concepts. The identified groups could then be used to inform the authoring of instructional tasks and within-task instructional strategies and feedback for each group as opposed to each learner, which would be a much more expensive process. Learning such individualized strategies for each learner would be possible using automated methods, such as reinforcement learning, but they require substantially more experimental data which it is not have available.

The main clustering algorithm used in this study is the DP-means algorithm [4]. Its main advantage is identifying the number of clusters using a Dirichlet Process Mixture Model. After briefly presented related work and the context of our own work, what follows is a description of the DP-means algorithm. We then present details of the experiments and results. We conducted experiments using two types of data: binary and categorical responses. In addition, other clustering algorithms were employed to compare the results with those obtained with DP-means. We evaluated the performance of the resulted clusters using intrinsic, e.g., based on the silhouette index which measures the compactness of each cluster, and extrinsic methods, e.g., based on students' post-test scores derived from post-test responses which were not used to generate the clusters.

2. RELATED WORK

Clustering has been used in the past for analyzing education data as indicated by the research studies presented next. Bouchet and colleagues [1] have applied the Expectation-Maximization clustering algorithm on data collected from the MetaTutor ITS. MetaTutor scaffolds student's metacognitive skills while learning about the human circulatory system. The main objective of their clustering was reinforcing self-regulated learning via student profiling. The results consisted of three distinct clusters of students in terms of performance. The results have been analyzed using a MANOVA approach.

Rodrigo and colleagues [8] have applied k-means clustering on data collected from students interacting with Aplusix, an ITS for Algebra. The main research goal of their work was identifying students' behaviors through an analysis of interaction logs. The results have demonstrated the existence of two clusters of students

Nisrine Ait Khayi and Vasile Rus "Clustering Students Based on Their Prior Knowledge" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 246 - 251

associated with differing behavior and affective states. The first cluster reflected more collaborative work whereas the second cluster reflected more solitary work.

Reyes-Gonzalez and colleagues [7] have used the LC-Conceptual clustering algorithm from logical combinatorial pattern recognition for student modeling in an ITS. This algorithm is based on two phases: the first phase consists of building groups of objects based on their similarity and a grouping criterion. The second phase is called the intentional structure phase where the distinctive features of each resulted cluster are determined. Fang and colleagues [3] have used k-means clustering to capture learning patterns in over 250 students who used AutoTutor to gain reading comprehension skills. The average response times per question and performance across lessons have been used to cluster the students' learning behavior. The results showed the convergence of four types of learners: proficient readers, struggling readers, conscientious readers and disengaged readers. Classifying readers can improve the adaptivity of AutoTutor ITS by providing a proactive feedback and intervention based on the learning behaviors.

Similar to those other approaches, our intention was to discover groups of students with similar knowledge states as characterized by their responses to the multiple-choice pre-test. Each incorrect choice in the pre-test is associated with a major misconception and therefore students that pick similar choices should be assigned to the same cluster. The centroid of the cluster could then be used to interpret the strengths and weaknesses of students in that cluster and appropriate interventions designed for that group.

3. CONTEXT OF THIS WORK

Our work was conducted in the context of an experiment in which high-school students interacted with a dialogue-based intelligent tutoring systems that tutors students on science topics through problem-solving. The system encourages students to self-explain solutions to complex science problems and only offers help, in the form of hints, when needed, e.g., when the student is floundering. That is, during a typical tutorial session, the system challenges students to solve a number of problems that are carefully selected by the system in order to optimize student learning (macro-adaptivity). When working on a particular problem, students are first asked to provide a solution that must include a justification based on concepts and principles of the target domain, which was Newtonian Physics in the case of our study presented here. All other things equal, low knowledge students will most likely struggle to provide solid self-explanations and most likely to articulate misconceptions which would lead to more scaffolding dialogue moves in terms of hints and correcting misconceptions on the part of the computer tutor (micro-adaptation). High knowledge students would need less scaffolding and therefore the corresponding dialogues should be shorter.

Before students start interacting with the system, they took a pre-test to assess their initial knowledge state. The tool elected to assess students' initial knowledge state was an enhanced version of the Force Concept Inventory (FCI). The Force Concept Inventory (FCI) is a 30-item multiple-choice "test" designed to assess student understanding of the most basic concepts in Newtonian mechanics (Halloun, Hake, and Mosca, 1995). The FCI presents students with various situations and ask them to choose between Newtonian explanations for the phenomena, versus common-sense alternatives (Hestenes, Wells, & Swackhamer, 1992). The FCI has been widely used to measure learning in introductory physics courses. For example, Hake (1998) reported FCI data from 6,000 high school

and university students. Coletta and Phillips (2005) combined their data with data collected by Hake (1998) and in combination used the FCI to measure learning in 73 university and college introductory physics classes. The data we have is based on an augmented version of the FCI consisting of 35 multiple-choice questions. The augmented FCI adds a number of questions for certain Newtonian topics which were not covered enough in the original FCI test.

We administered the augmented Force Concept Inventory (aFCI) to students at three public and two private high schools in the mid-south region, including six teachers and 26 classrooms. The pretest was administered in classroom. Students completed the aFCI via provided scantron sheets, which were then collated and processed. The results of the scantron sheets were then compared to direct markings on the actual aFCI test in the case of blank or unidentifiable scantron responses. The data collection process was quite successful, resulting in 444 students with complete pretest data. We only used a subset of 265 students in our experiments because post-test data, used for extrinsic evaluation of our clustering, was available only for those 265 (the rest of the students either missed a tutoring session, or the post-test, or both).

It should be noted that the data is very diverse in terms of student prior knowledge of physics because students were recruited from a large variety of physics-related courses including introduction to physics, honors physics, and AP physics. This should allow us to draw general conclusions

4. DP-means BASED CLUSTERING

The DP-means algorithm, as described by Kulis & Jordan [4], is a hard-clustering approximation of nonparametric Bayesian models. Under the assumption that the DP-means is derived from a Dirichlet Process Mixture Model, there exists a lambda value α such that when used by the algorithm, the number of clusters k is identified. The DP-means algorithm is similar to the k-means clustering algorithm except that a new cluster is generated when the distance from a data point to the nearest cluster is larger than the threshold α .

Specifically, the DP-means algorithm is derived from a Dirichlet Process Mixture Model (DPMM) as illustrated below:

- $\mu_1, \dots, \mu_k \sim G_0$
- $\pi \sim \text{Dir}(k, \pi_0)$
- $z_1, \dots, z_n \sim \text{Discrete}(\pi)$
- $x_1, \dots, x_n \sim N(\mu_{z_i}, \sigma I)$
- The Dirichlet prior of dim k is placed using some π_0

where:

- μ is the mean of each of the clusters, drawn from some base distribution G_0 , which is the prior distribution over the means.
- $\pi = (\pi_1, \pi_2, \dots)$ corresponds to the vector of probabilities of being in a cluster.
- z_i is an indicator of cluster assignment.
- x_i is a data point

The corresponding clustering algorithm is described in Figure 1. The input consists of data instances x_1, \dots, x_n , where x_i represents the vector of pre-test answer choices of the i^{th} student. Since the pre-test contains 35 questions, each such response vector x_i contains 35 entries corresponding to each answer choice picked by

student i . The clustering algorithm begins by initializing a single cluster whose mean is the global centroid. Then, it initializes a set of cluster indicators: $z_i = 1$ for all $i = 1, \dots, n$ where $z_i = k$ means that the student x_i belongs to the k^{th} cluster as denoted by l_k .

In step 3, the algorithm computes the distances between each data point and the existing centroids. It then compares the minimum of these distances with α . If the minimum is larger than the threshold α , a new cluster is generated, and its centroid is assigned the current data point x_i . Otherwise, the cluster indicator of the current data point is set to the $argmin$ of the distances. After looping over all data points, the number of clusters k and the clusters indicators are computed. Finally, the DP-means algorithm generates the clusters l_j and their centroids μ_j for $j = 1, \dots, k$. Step 3 is repeated until the algorithm converges.

Algorithm: DP-means
Input: x_1, \dots, x_n : input data, α : cluster penalty parameter
Output: Clustering l_1, \dots, l_k and number of clusters k
1. Init. $k = 1, l_1 = \{x_1, \dots, x_n\}$ and μ_1 the global mean.
2. Init. Cluster indicators $z_i = 1$ for all $i = 1, \dots, n$
3. Repeat until convergence
• For each point x_i
- Compute $d_{ic} = \ x_i - \mu_c\ ^2$ for $c = 1, \dots, k$
- If $d_{ic} > \alpha$, set $k = k + 1, z_i = k$, and $\mu_k = x_i$
- Otherwise, set $z_i = argmin_c d_{ic}$
• Generate clusters l_1, \dots, l_k based on z_1, \dots, z_k :
$l_j = \{x_i \mid z_i = j\}$
• For each cluster l_j , compute $\mu_j = \frac{1}{ l_j } \sum_{x \in l_j} x$.

Figure 1. DP-means algorithm

4. EXPERIMENTS AND RESULTS

4.1 Dataset

The data used in our experiments consists of pre-test answers collected from 264 high-school students who took the aFCI pre-test, went through a 5-week training period, and then took a post-test. Furthermore, after each training sessions students took a short post-test (6 questions). In all our experiments, we will use this post-test after the very first training session as the extrinsic evaluation criterion as it is closest in time (among all post-tests) to the pre-test and therefore is a good estimate of students' early knowledge states as best captured by the pre-test. The pretest includes 35 multiple choice questions that have the same weight. Two types of data have been used in our experiments: 5-way response data and binary response data. The categorical data consists of the actual answer choices students picked for the 35 multiple choice questions coded as A, B, C, D and E. For each question, one those choices is the correct answer. The binary data represents the same data coded as binary correctness values: 0 – incorrect, i.e., the student picked any of the incorrect answer choices, and 1 – correct, i.e., the student picked the correct answer choice.

Tables 1 and 2 illustrate the data representation for the two tables. As described below, the columns represent the 35 questions and the rows represent individual students' responses.

Table 1. Categorical data

Dh002	1	0	...	1
...
DH356	1	0	...	0

4.2 Experiments: Binary data

A first set of experiments have been conducted using the binary data as input for the DP-means algorithm. Since we have binary data and DP-mean is based on the Euclidean distance, we have applied Principal Component Analysis (PCA) to convert the binary values to continuous ones. For this purpose, numerous values of n (number of components) have been tested. The value 35 led to a convergence state of 10 clusters in which several clusters are redundant, i.e., using the extrinsic criterion based on the overall post-test score. For example, the average of the post test score for clusters 6, 7 and 9 is 3.0. Thus, we have tested randomly several values. The value 24 led to better clustering results in terms of splitting well the clusters based on the extrinsic criterion. Thus, we used those components to represent our data points for the rest of the experiments. On the binary data, a Manhattan distance could be used which we tried and didn't lead to better results than the above method of using PCA.

The α distance parameter has not been defined a priori. To select a suitable value of this parameter, we followed first the procedure described by Kulis and colleagues [4] as in the following: given $k=3$ as the desired number of clusters, we first initialize a set A with the global mean of the data. Then iteratively we calculate the maximum distance to A (the distance to A is the smallest distance among points in A). We repeat this $k (=3)$ times and assign to α the value of the maximum distance to A. In our work, we got the value of 3.26. Testing the DP-means with this value led to the convergence of two clusters of students. To reach the desired number of clusters which is 3, we have tried other values in a close interval of [3.26, 2.8] as described in Table 3.

Thus, various values have been tested and compared. The evaluation of the resulted clusters has been done using the following measures:

- Silhouette index: Its value measures how similar a student response vector (her set of responses to the pre-test questions) is to its own cluster (cohesion) relative to the other clusters (separation). The silhouette index is a value within the $[-1, +1]$ interval. A high value of the silhouette index indicates that the student is well matched with the other students in the same cluster. The following metric distances have been tested:

Euclidean distance, Manhattan distance and cosine similarity. The obtained results have shown that the Euclidean distance led to better results as demonstrated in Table 3.

- Mean of post test score: The data collected from the interaction of the students with the ITS includes post test scores for the 264 students. Since the post test is taken at the end of the experiment, weeks after the students took the pretest, and since it has not been used in the cluster, it can be used as an extrinsic measure of cluster validity and interpretation of the resulting clusters. Indeed, this measure is used by us to assess the mastery level of each resulted cluster of students. In addition, it has been used as a way to check the separation of the clusters. The maximum and minimum values of the post test score in this collected data are 6.0 and 0.0 respectively.
- Mean of pretest score: The data collected includes the pretest performance of each student based on of the correct answers. The highest value is 35 and the lowest value is 0.

Table 3 offers a set of results of DP-means clustering using different types of distances.

Table 3. clustering results with different types of distances

Distance	α	Number of clusters
Manhattan	2.9	255
	3.0	255
	3.1	255
Euclidian	2.9	5
	3.0	3
	3.1	2
Cosine	2.9	1
	3.0	1
	3.1	1

Table 4. DP-means clustering results with different values of α

α	Clusters	Mean pretest score	Mean post-test score	Number of students
2.9	C1	15.26	3.31	207
	C2	31.28	5.66	36
	C3	6.47	1.89	19
	C4	25.0	5.0	1
	C5	14.0	2.0	1
3.0	C1	17.68	3.44	195
	C2	31.11	5.64	37
	C3	8.83	1.62	32
3.1	C1	13.87	3.18	277
	C2	29.54	5.64	37

Figure 2. Quality of the DP-means algorithm using different values of α

The results in Figure 2 show that the value 3.0 of parameter α led to the highest value of the Silhouette index (0.27). In addition, this α value resulted in three distinct clusters, well separated (Figure 3), in terms of students' performance in the post test and pretest (as described in table 4). The first cluster contains 195 students. The mean post test score is 3.44 and the mean pretest score is 17.68 which are average scores. Students who belong to this cluster can be described as average performers or learners. The second cluster contains 37 students. The mean post test score is 5.66 and the mean pretest score is 31.11 which are high scores. The students in this cluster can be described as high performers or learners of Physics. The third cluster contains 32 students. The mean post test score is 1.625 and the mean pretest score is 8.83 which are very low scores. The students of this cluster can be describing as struggling ones.

Figure 3. DP-means visualization with $\alpha = 3$

Figure 4. DP-means visualization with $\alpha = 3.1$

Figure 5. DP-means visualization with $\alpha = 3.2$

To compare the results of the DP-means algorithm with other clustering algorithms, we have also applied the k-means and agglomerative clustering algorithms on the same binary data. Since the best result of the DP-means was for an α value 3.0, we ran the k-means algorithm using $k=3$ and the agglomerative clustering using the same number of clusters ($=3$). Tables 5 and 6 present the results for k-means and agglomerative clustering, respectively.

Table 5. k-means results

Clusters	Mean Post-Test Score	Mean Pretest Score	Number of students
C1	2.28	9.44	97
C2	5.21	28.84	52
C3	3.83	17.22	115

Figure 6. Quality of the DP-means algorithm using different values of α .

Table 6. Agglomerative clustering results

Clusters	Mean Post Test Score	Mean Pretest Score	Number of students
C1	3.55	16.46	165
C2	5.45	30.0	42
C3	2.07	8.28	57

The results depicted in Table 4 show that the DP-means algorithm with $\alpha=3.0$ outperforms the k-means and the agglomerative algorithms as described in tables 5 and 6 respectively. The difference, in the mean post test score and the mean of pretest score, between the clusters of DP-means is larger than the difference using the other clustering algorithms. This indicates the convergence of well separated groups of students, in terms of learning level and prior knowledge, when applying the DP-means.

A detailed analysis of the top 10 students closest to the centroids of each of the three clusters found by DP-means, revealed that students in cluster 1 struggled mostly with questions related to Newton's third and first laws, whereas students in cluster two struggled with questions related to Newton's third law. Students in cluster 3 struggled the most and they showed weaknesses across all major topics in Newtonian Physics. Since in this experiment we used just correctness values for each pre-test question it is not possible to provide a more detailed analysis in terms of specific misconceptions, e.g., assuming faster velocity implies a larger force in an action-reaction pair, students in each clusters exhibit.

4.4 Experiments: Clustering categorical data

A second set of experiments have been conducted using categorical data and the DP-means and K-modes clustering algorithms. That is, in this case, we used the actual answer choices picked by students for the pre-test questions in order to find the clusters.

To this end, first, we have converted the categorical responses to numerical ones using one-hot encoding. Basically, each answer choice becomes a dimension in a vector space representation. A value of 1 is assigned to that dimension for a given question in the pre-test if a student picked the choice corresponding to the dimension as their answer choice. This results in an encoding of categorical integer features as a one-hot numeric array. The encoder derives the categories based on the unique values in each feature. The output of the one-hot-encoding is fed into the clustering algorithms.

The results presented in Table 7 reflect a decrease in quality of the DP-means clustering using categorical data. The silhouette index, as described in Figure 6, has decreased in comparison with the DP-means based on binary data. The highest value was 0.06 when using the value 4.4 of α . The different values of α didn't lead to a good split of students in terms of the performance. For example, in the case of $\alpha = 4.4$, cluster C2 and C3 can be merged in one cluster since their mean post test and pretest scores are very close. For $\alpha = 4.3$, there is redundancy in the resulted clusters. For example, C3 and C6 can be merged in one cluster.

Table 7. DP-means clustering results (categorical data) with different values of α

α	Clusters	Mean Post Test Score	Mean Pretest Score	Number of students
4.3	C1	4.17	20.39	68
	C2	1.5	5.5	67
	C3	1.0	10.0	1
	C4	2.0	4.5	54
	C5	2.0	6.0	40
	C6	1.66	6.0	22
	C7	2.16	9.35	12
4.4	C1	4.12	20.14	187
	C2	1.0	10.0	1
	C3	1.66	6.0	3
	C4	2.15	9.0	73
4.5	C1	3.55	16.87	263
	C2	1.0	10.0	1

In order to overcome this drawback of DP-means when applied to categorical data, we have applied the k-modes clustering algorithm [5, 6]. The k-modes algorithm is based on defining the dissimilarity measure between objects. This dissimilarity between two objects A and B can be defined by the total mismatches of the corresponding attribute categories of the two objects. The smaller the number of mismatches is, the more similar the two objects. The dissimilarity measure is calculated using the following equation:

$$d(X, Y) = \sum_{j=1}^m \delta(x_j, y_j) \quad (1)$$

where:

$$\delta(x_j, y_j) = \begin{cases} 0 & (x_j = y_j) \\ 1 & (x_j \neq y_j) \end{cases} \quad (2)$$

The following are the results with k-modes when using $k = 3$.

Table 8. Kmodes results with $k = 3$

Clusters	Mean Post Test Score	Number of students
C1	3.72	120
C2	5.03	59
C3	2.23	85

The results listed in Table 8 demonstrate that the k-modes outperforms the DP-means when using categorical data. The

resulted clusters reflect a good split between clusters in terms of performance in the post test. The C1 cluster reflects an average knowledge level of students. C2 reflects a high level of knowledge of students. And C3 reflects a low level of learning. A more detailed analysis indicates the same overall conclusions reached using the correctness data, e.g., students in cluster one struggle mostly with Newton's second and third laws. However, when using the categorical data, we can further pinpoint which aspects of Newton's third law for instance, students struggle with. For instance, many students in cluster C1 seem to struggle with the misconception that in an interaction between two objects the more massive one will act with a bigger force on the smaller one which is not true. According to Newton's third law, to each action there is an equal and opposite reaction. Therefore, this analysis suggests that when a new student uses a Physics ITS, after they take the pre-test and their answer patterns place him closer to the centroid of cluster C1, i.e., in cluster C1, then appropriate instructional tasks that have been designed for students in that cluster should be activated in order to overcome major gaps students in that cluster exhibit.

5. CONCLUSIONS

In this work, DP-means clustering algorithm has been applied on the pretest data of 264 students collected from their interaction with DeepTutor ITS. Various values of α have been tested. The results demonstrated that 3.0 is the best value and three distinct clusters of students have been converged. These clusters reflect three distinct levels of learning which has been assessed using post test scores. The first cluster of students correspond to an average level of learning, the second cluster represents students with a high level of learning and the third cluster of students those with a low level of learning. Results have demonstrated also that DP-means outperforms k-means and Agglomerative clustering in terms of splitting well students based on their performance in the post test. Another finding is that the quality of DP-means algorithm, measured by the silhouette index, decreases when we use the categorical data in comparison with the binary data. To overcome this drawback, we have used the k-modes clustering.

Furthermore, such clustering could offer a good trade-off between adaptivity and authoring costs. For instance, macro-adaptation can be expensive if the number of unique student knowledge states is very large as it requires selecting a unique set of tasks for each such unique knowledge state. Concretely, if using a 5-way/choice 35 multiple-choice question pre-test, the number of possible combinations of 35 answers is 5^{35} , an extremely large space. That is, if each student's knowledge state is described by the 35 responses we end up with 5^{35} student knowledge states or student models which, by comparison, is much larger than the world's population which is a bit over 5^{14} . Considering each of these potential knowledge states and selecting for each corresponding learner a unique set of tasks becomes a computationally and authoring challenge. An alternative, for instance, would be to group students into clusters of similar mental models and then select and author tasks for each such clusters. That is, grouping students into similar mental model groups can offer a good trade-off between adaptivity and authoring costs.

We plan to further investigate the resulting clusters for a better understanding of the characteristics of the students in each cluster. For instance, we do have information about the Physics class (intro, honors, AP) each student took and therefore a detailed analysis for students in each cluster based on their class type can be performed in order to understand what are the major misconceptions students

in each class struggle with. Not only this could inform an ITS for Physics, but this information can be shared with teachers in order to help them better plan their lessons plans to address major misconceptions their students may have.

ABSTRACT

Understanding exam score distributions has implications for item response theory (IRT), grade curving, and downstream modeling tasks such as peer grading. Historically, grades have been assumed to be normally distributed, and to this day the normal is the ubiquitous choice for modeling exam scores. While this is a good assumption for tests comprised of equally-weighted dichotomous items, it breaks down on the highly polytomous domain of undergraduate-level exams. The logit-normal is a natural alternative because it has a bounded range, can represent asymmetric distributions, and lines up with IRT models that perform logistic transformations on normally distributed abilities. To tackle this question, we analyze an anonymized dataset from Gradescope consisting of over 4000 highly polytomous undergraduate exams. We show that the logit-normal better models this data without having more parameters than the normal. In addition, we propose a new continuous polytomous IRT model that reduces the number of item-parameters by using a logit-normal assumption at the item level.

1. INTRODUCTION

Historically, student performance on exams has been assumed to be normally distributed. Grade curving originates from the idea that students exist on a “bell curve,” in which most are clustered around the mean and a small number over- or under-achieve. The field of education has many criticisms for the bell-curve mindset. A common argument is that we should not take the *observation* that student performance tends to look normal and turn it into a normative practice [4, 23]. The idea that some students will inevitably fail and only a small number can enjoy the highest level of success runs counter to the goals of the educator, who should want as many students as possible to succeed. This tension plays out in the ideological battle between those who criticize grade inflation [9] and those who suggest that students may be earning the higher grades they are receiving [11].

Noah Arthurs, Ben Stenhaus, Sergey Karayev and Chris Piech "Grades are not Normal: Improving Exam Score Models Using the Logit-Normal Distribution" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 252 - 257

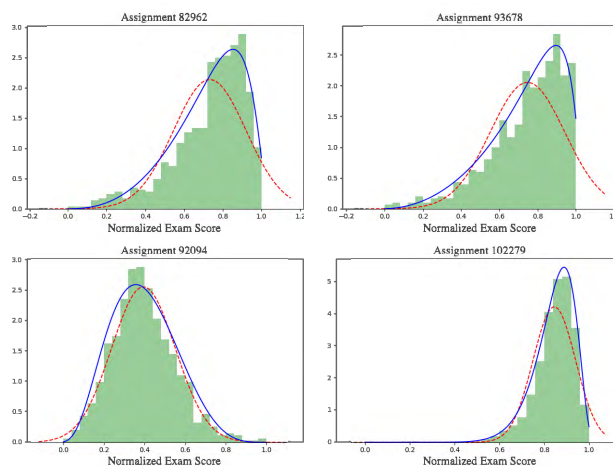

Figure 1: Score histograms of four assignments, along with the PDFs of the best-fit normals (dashed red) and best-fit logit-normals (solid blue).

The normal assumption is commonplace in modern research into educational data. Grade distributions are usually presented to students in terms of their mean and variance, and they are often visualized as normal distributions [17]. As education becomes more digitized, statistical models of grading become more widespread. For example, peer grading models allow MOOC’s to assign accurate grades to students based on noisy estimates from their classmates. State of the art peer grading models use normal priors over grades [19, 18], which will result in normal-looking distributions. Both of these examples can benefit from challenging the normal assumption. In the first case, finding new ways to parameterize grade distributions can help us better interpret and visualize student behavior. In the second, a more accurate prior over grades would help peer grading models assign more accurate grades to students.

In this paper, we analyze over 4000 assignments graded on the Gradescope platform [22]. These assignments are primarily exams from undergraduate STEM courses, and as a result the data is highly polytomous (many scoring categories per question). However, principal component analysis (PCA) reveals that these exams have good low-rank approximations, meaning that the data is very structured.

First, we examine the ability of different families of distributions to model the scores in our dataset. Specifically we compare the normal to three bounded two-parameter distributions. We find that the logit-normal [1, 5] is consistently the best choice, followed by the beta, which is known to approximate the logit-normal [8].

In the second part of this paper, we build a simple continuous polytomous IRT model using a logit-normal assumption at the item level. Our model outperforms both the Generalized Partial Credit Model [16] (a standard discrete IRT model) and the Continuous Response Model [20] (a standard continuous IRT model) on the Gradescope data, despite having fewer parameters than either. This indicates that we can simplify and improve polytomous IRT models using structural assumptions about assignment data.

1.1 Related Work

When analyzing student behavior, it can be difficult to distinguish between cases where data is actually normal and cases where an assumption of normality is influencing the distribution. For example, SAT scores are known to be normally distributed, but this is because raw SAT scores are translated into final scores using a system that enforces a normal distribution [3]. More subtly, probabilistic models for determining scores based on peer grades often use normal priors over their output [18, 19]. As a result, they will push grade distributions to be normal. The question then remains about whether these distributions *should* look normal in reality or another prior needs to be found.

Of course, grade curving is the most direct way in which student performance is influenced to be normal. Although it remains a common practice, research has shown that most students prefer not to be graded on a curve [6], that both students and professors find indiscriminate grade curving unethical [15], and that grade curving can amplify the randomness of test-taking as a measure of student aptitude [12]. It has also been argued that educators should be striving to avoid normally distributed student outcomes, rather than enforce them [4, 23]. If this is the case, then we need to actively seek out new distributions for describing and understanding test scores.

Polytomous IRT models generally fall into two categories. Discrete models like Generalized Partial Credit [16] and Graded Response Models [21] model each point on each question separately, scaling with the number of scoring categories per question. These models make very few assumptions about the relationship between different scores and thus do not take advantage of any underlying structure in the data. Continuous models like the Continuous Response Model [20] are used less frequently, but they scale only with the number of questions in the assignment. They do this by making assumptions about the structure of the item characteristic curves (ICC's). This means that if a dataset's ICC's follow a consistent pattern, then a continuous model can thrive.

The Gradescope data we are working with is much more polytomous than most IRT datasets. This is because it comes from a wide variety of college-level courses rather than standardized tests. Despite this heterogeneity, past work on Gradescope data has found patterns in question

ordering and the interpretation of the first several principal components [13]. This indicates that there may be underlying structure that a continuous IRT model could take advantage of.

2. THE DATASET

Our initial dataset consists of 6,607 assignments submitted to Gradescope, an online tool for uploading and grading student work [22]. Typically students will do their assignments by hand using a template provided by the instructor. After the assignments have been scanned and uploaded to Gradescope, instructors can grade them using a digital rubric that is always visible and modifiable. To ensure that the majority of the data consists of college-level exams, all included assignments:

- are instructor-uploaded¹
- have a fixed template
- have at least 3 questions
- have titles that do not include terms that describe other kinds of student work (e.g. “HW” or “Quiz”)
- have titles that do not include terms that are indicative of non-college-level work

The assignments were graded between Spring 2013 and Spring 2018, and come from 2748 courses at 139 different higher-education institutions². The top three subject areas in the dataset are Electrical Engineering & Computer Science (50% of assignments), Math & Statistics (22%), and Chemistry (11%). The median number of courses per school is 4, and the median number of assignments per course is 2.

When fitting curves to exam scores, we want there to be enough values that the distribution is interesting/nontrivial and enough data points that the observed histogram is somewhere near the underlying distribution. For this reason, we filter out all assignments that have fewer than 10 unique scores or fewer than 75 students. We are then left with 4115 assignments. Figure 2(b) shows the joint distribution between student count and number of unique scores, as well as their marginals. Observe that the vast majority of assignments have 75-200 students and 20-80 unique scores.

Throughout this study we store each assignment as a matrix A where A_{ij} represents student j 's score on question i . We use the term “exam score” to refer to the sum of a student's question scores, so to analyze exam scores, we sum the rows of the assignment matrix A .

2.1 Visualizing the Data

One shortcoming of the normal is that it can only represent symmetric distributions.³ We measure the symmetry of an exam score distribution using skew (skewness), which can be

¹On Gradescope, students tend to upload their own homework, while exams tend to be scanned and uploaded by the instructor.

²However, UC Berkeley, UC San Diego, Stanford University, University of Michigan, and University of Washington account for half of all assignments in the dataset.

³This may not be a problem on all forms of test data. For example, if questions were equally weighted and (relatively) independent, the Central Limit Theorem would predict a symmetric distribution.

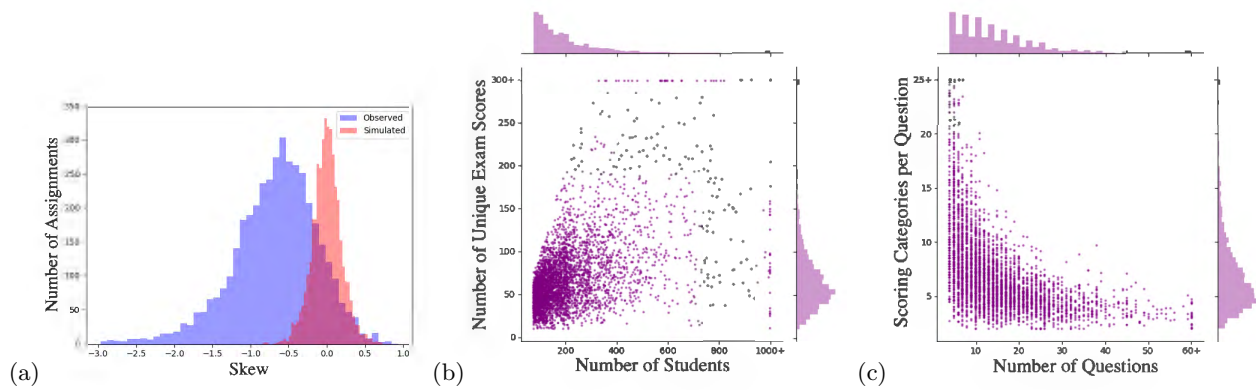

Figure 2: (a) Normal doesn’t fit. Blue histogram: assignment skew distribution. Red histogram: skews of assignments had they been drawn from normal distributions (as described in section 2.1). (b) Number of students vs. number of unique exam scores for each assignment in the filtered dataset. (c) Number of questions vs. average number of scoring categories per question for each assignment in the filtered dataset.

a good indicator of how normal a distribution is [2]. A skew value of (or near) 0 indicates a symmetric distribution, while negative and positive skew values indicate large tails on the left and right respectively. The blue histogram in Figure 2(a) shows the skews of the exam score distributions in our dataset. Note that they tend to be negative, meaning that exams tend to have larger tails of below-mean students than of above-mean students. To generate the red histogram in Figure 2(a), we performed the same experiment on a simulated dataset created by redrawing the scores of each assignment from its best-fit normal⁴. The large difference in both mean and variance of these histograms shows that our observed skews would not be very likely were the data normally distributed. In order to quantify this intuition, we performed a D’Agostino’s K-squared test of normality to determine how likely it would be for each assignment’s skew to arise from a normal distribution [2]. We found that 73% of assignments had a p-value of 0.05 or lower, indicating that (just on the basis of skew) the vast majority of assignments are very unlikely to have come from a normal distribution.

When fitting IRT models to the assignments, we are interested in how polytomous each assignment is. Figure 2(c) shows the joint distribution between the number of questions an assignment has and the average number of scoring categories per question. The negative correlation between these two stats is unsurprising⁵, but it means that we can test our models on highly polytomous items or large question-counts but not both at the same time.

2.2 Dimensionality

PCA [10] can give us insight into the dimensionality of our data. A previous use of PCA on Gradescope data [13] found that the first principal component distinguishes between high and low scoring students, while later principal components correspond to skill at particular types of questions (e.g. multiple choice, free response).

⁴If an assignment had n students, sample mean \bar{x} and sample variance S , our simulated version of that assignment would consist of n draws from $N(\bar{x}, S)$.

⁵There are only so many points that a student could be expected to earn over the course of a single exam.

We use PCA to describe the dimensionality of a given exam, where dimensionality is defined as the number of principal components required to account for 80% of the variance between students. Put simply, we are interested in what rank is required to form a “pretty good” approximation for the exam matrix. Intuitively, if exams have low dimensionality, then they have a large amount of structure we can exploit when modeling them.

We find that number of students and number of questions (the two dimensions of our exam matrix) do not influence dimensionality in the same way. Number of students is weakly correlated with dimensionality (0.20 Pearson correlation), and on average it requires over 250 extra students to add a dimension. Number of questions, on the other hand is more strongly correlated (0.85 Pearson correlation), and one dimension is added every 3.3 questions. This is consistent with the finding in [13] that principal components correspond to specific student aptitudes. Overall, this analysis indicates that choice of model should be based on the features of the exam itself, not on how many students are taking it.

We also examined the first principal component in isolation, and found that it generally indicated a student’s score. Across our dataset, the average magnitude of the Pearson correlation between exam score and the first principal component was 0.965. In addition, the first principal component on average accounts for 43% of the variability in an assignment. The strength of the first principal component indicates that IRT models might only need one-dimensional student ability parameters to be successful on this dataset.

3. FITTING EXAM SCORES

Our first modeling task is to compare the ability of different two-parameter distributions to fit the exam scores in our dataset. Since tests have minimum and maximum scores, we choose bounded distributions. In addition, due to our findings in 2.1, we choose distributions that are not symmetric.

3.1 The Distributions

The truncated normal distribution is the result of bounding the normal above and below. It is characterized by the

	Normal	Trunc	Beta	Logit
Beats Normal	-	100%	92%	87%
Beats Trunc	0%	-	67%	75%
Beats Beta	8%	33%	-	68%
Beats Logit	13%	25%	32%	-
Average LL	0.272	0.333	0.336	0.353

Table 1: Win Rates and Likelihoods: How often does each distribution outperform the others? The logit-normal, beta and truncated normal models are all better replacements for the normal distribution. logit-normal has the highest likelihood.

mean and variance of its underlying normal, and when the bounds are known, there is a closed form maximum likelihood (MLE) estimate of these parameters [7]. The truncated normal assigns a higher probability density to every value in its domain than its underlying normal does, and as a result it will strictly outperform the normal distribution in likelihood. Although it is not symmetric around its mean, if it includes the mean of the underlying normal, then its probability density function (PDF) will be mirrored across that point. The truncated normal will be a good fit if test scores are drawn not from a normal distribution but from a slice of a normal distribution.

The beta distribution is the conjugate prior of the Bernoulli, characterized by two parameters referred to as α and β . It has no closed form MLE estimates, but there is a closed form method of moments solution that can be used as a starting point for optimization. When $\alpha = \beta$, the beta has no skew, but it can achieve a wide range of skew values by varying the difference between the two parameters. The beta does not have an intuitive interpretation in this context.

The logit-normal distribution [1, 5] is the result of applying the sigmoid (logistic) function⁶ to data sampled from a normal distribution. Like the truncated normal, its parameters are the mean and variance of its underlying normal. The logit-normal and beta are known to approximate each other [8], but the logit-normal comes with the advantage of having closed form MLE estimates of its parameters⁷. It also has a nice interpretation that comes from item response theory. Logistic IRT models like 1PL/2PL/3PL take normally-distributed student abilities and use a linear transformation plus a sigmoid to transform them into probabilities. If the logit-normal is a good fit for exam scores, we can see it as performing the same kind of transformation to go from an underlying unbounded variable to an observed bounded one.

In addition to these, we tried a Two Gaussian Mixture Model in case distributions were bimodal. However, it performed worse than all three of these distributions despite having more parameters, so we did not include it in our results.

⁶The sigmoid, given by $\sigma(x) = \frac{1}{1+e^{-x}}$ compresses the reals into the range (0, 1). Its inverse, the logit function given by $\sigma^{-1}(p) = \log \frac{p}{1-p}$, does the opposite.

⁷Unsurprisingly, the MLE estimates for the mean and variance of the underlying normal are the mean and variance of taking the logit (σ^{-1}) of the exam scores.

Figure 3: Difference in performance between the candidate distributions across sample sizes. Bands show standard error. Assignments were downsampled to simulate lower student counts.

3.2 Evaluating the Distributions

We fit each of the three distributions above plus the normal to each of the 4115 sets of exam scores in our filtered dataset. In order to more easily fit our bounded distributions to the data, we compress all scores into the range [0.05, 0.95]⁸. Specifically, if we have observed exam scores x_1, \dots, x_N , we map each x_i to

$$x'_i = 0.9 * \frac{x_i - x^{min}}{x^{max} - x^{min}} + 0.05$$

where $x^{min} = \min_i x_i$ and $x^{max} = \max_i x_i$. We use MLE parameter estimation to fit the distributions and evaluate them using log likelihood, defined as

$$LL(\theta) = \frac{1}{N} \sum_{i=1}^N \log f(x'_i | \theta)$$

where f is a PDF parameterized by θ^9 . We obtain the same semantic results when we use Earth Mover's Distance instead of Log-Likelihood as our goodness of fit metric.

3.3 Distribution Results

After performing this experiment, we find a clear hierarchy with the logit-normal performing best, followed by the beta, then the truncated normal, then the normal. Table 1 shows this hierarchy in two ways. First, the average log likelihood across assignments increases from left to right. Second, we can see that the logit-normal is a better fit than the beta 67% of the time, the beta is a better fit than the truncated normal 67% of the time, and the truncated normal is a better fit than the normal 100% of the time¹⁰. It is a little bit surprising that the beta outperforms the normal slightly more often

⁸[0, 1] may seem like the more natural choice, but both the beta and the logit-normal perform poorly when values are close to 0 or 1 (with the logit-normal unable to produce 0's and 1's at all).

⁹Note that because the PDF's are constrained to the range 0 to 1, our log likelihoods will come out positive.

¹⁰As mentioned above, this is because the truncated normal's PDF lies strictly above the PDF of its underlying normal.

	Baseline	GPCM	CRM	LNM
Parameters/Item	0	B + 1	3	2
Average RMSE	0.307	0.258	0.278	0.255

Table 2: Loss for each IRT model measured across 4115 assignments. “B” refers to the number of scoring categories for a given item.

than the truncated normal does, but this is the only result in Table 1 that is inconsistent with our proposed hierarchy.

Figure 3 shows that our conclusion that the logit-normal is the best choice is robust to sample size. All distributions fit better as sample size increases, since larger numbers of students result in smoother score histograms.

4. LOGIT-NORMAL IRT

Many of our results so far indicate that highly polytomous exam data is also highly structured. Polytomous IRT schemes like the Generalized Partial Credit Model (GPCM) [16] and Graded Response [21] scale with the number of scoring categories per question and thus do not take advantage of structure in the shapes of the item characteristic curves. On the other hand, continuous models like the Continuous Response Model (CRM) are able to cut down on parameters by assuming a parameterized function for each ICC. In this final section, we will propose a continuous model that uses logit-normals to make such simplifying assumptions and thus take advantage of the underlying structure of our data.

We find that when it comes to fitting exam scores, the logit-normal is just as successful when there are smaller numbers of unique scores available. Our model pushes that idea to its limit by modeling each question on an exam with a single logit-normal. The assumption is that highly polytomous items will behave like mini exams and as a result logit-normals will describe them well.

Our model fits a single ability $\theta_j \in \mathbb{R}$ to each student j and (as alluded to above) fits a logit-normal distribution to each item i with parameters μ_i and σ_i . Let S_i represent a random student’s score on question i , and let S_{ij} represent student j ’s score on question i . Our parameters are then related by the following equations:

$$\begin{aligned}\theta &\sim N(0, 1) \\ S_i &\sim \text{Logit-Normal}(\mu_i, \sigma_i) \\ E[S_{ij}] &= \sigma(\sigma_i \theta_j + \mu_i)\end{aligned}$$

As in section 2, we refer to our observed data as a matrix A where A_{ij} stores student j ’s score on question i . In addition, we assume that the data has been shifted and scaled as described in section 3.2. We fit this model in two steps:

1. Use MLE estimation to choose each μ_i and σ_i to fit the observed distribution of S_i ’s. Specifically, if A_i is the vector of observed scores on question i , we set μ_i and σ_i to be the sample mean and sample standard deviation of $\sigma^{-1}(A_i)$.¹¹

¹¹Here we are applying the logit function σ^{-1} element-wise.

2. Choose each θ_j to minimize the total squared error of the $E[S_{ij}]$ ’s. Specifically:

$$\begin{aligned}\theta_j &= \operatorname{argmin}_{\theta} \sum_i (E[S_{ij}] - A_{ij})^2 \\ &= \operatorname{argmin}_{\theta} \sum_i (\sigma(\sigma_i \theta_j + \mu_i) - A_{ij})^2\end{aligned}$$

We use least squares to fit the θ ’s because we have not defined a probability distribution over S_{ij} , which would be required to perform MLE. More research is required to determine what kind of probability distribution centered at $E[S_{ij}]$ will perform best.

4.1 Evaluating the IRT Models

We will evaluate our model based on how well it can use the parameters it has learned to predict student scores on each question. Note that in-sample evaluation is the norm for IRT [14]. Specifically we will measure the RMSE between the predicted $E[S_{ij}]$ ’s and the observed A_{ij} ’s. If an assignment has n students and m questions, this is calculated as:

$$RMSE(\theta, \mu, \sigma) = \left(\frac{1}{mn} \sum_{i=1}^m \sum_{j=1}^n (E[S_{ij}] - A_{ij})^2 \right)^{1/2}$$

4.2 IRT Results

Table 2 shows the comparison across the whole dataset between our Logit-Normal Model (LNM) and:

- a baseline that uses each student’s normalized exam score as a prediction for each question.
- a 2PL Generalized Partial Credit Model (GPCM) [16] fit using EM.
- a Continuous Response Model (CRM) [20] fit using the EM approach described in [24].

The fact that our model has the best performance despite having the fewest parameters indicates that it is taking advantage of the structure of highly polytomous items. We can conclude that discrete models are more complicated than necessary on data like this. We can also conclude that the assumptions about item characteristic curves in CRM are not as good as the logit-normal assumption on this data.

5. CONCLUSIONS

Overall, we have shown that highly polytomous exam data has a large amount of underlying structure that can help us simplify our probabilistic models. Out of three bounded, asymmetric candidates, the logit-normal came out on top as the best prior for exam scores. In addition, the logit-normal’s ability to model individual polytomous items allowed us to develop a polytomous IRT model that is simple and well-suited to this kind of data. We hope to have challenged the traditional assumption that the normal is the best prior for student behavior, and we hope that more work will be done to simplify IRT models for the highly polytomous data produced by college-level courses.

6. FUTURE WORK

The main loose end from this paper is the fact that we did not define full probability distributions over S_{ij} in the logit-normal model. Without these distributions, the model is

Figure 4: Joint distribution of σ and μ item parameters from the Logit-Normal Model.

able to predict scores and abilities but unable to act as a generative model. Future research needs to be done to find out what family of distributions best models S_{ij} . In addition, Figure 4 shows that there is a strong (somewhat ellipsoidal) relationship between the item parameters of our model, indicating that there may be further structure to exploit in highly polytomous items.

While our results are convincing in the highly-polytomous domain, more work is required to see how well they generalize to less polytomous data. In addition, the logit-normal needs to be tested on downstream tasks like peer grading in order to verify that it is an effective prior for exam scores.

In the interest of reproducibility, and to enable further science, the fully anonymized dataset used in this paper will be made available to other researchers for appropriate academic use. To gain access to the data, researchers must provide IRB approval documentation and must sign an agreement that ensures the anonymized data is treated appropriately.

Assessing Student Response in Tutorial Dialogue Context using Probabilistic Soft Logic

ABSTRACT

Automatic answer assessment systems typically apply semantic similarity methods where student responses are compared with some reference answers in order to assess their correctness. But student responses in dialogue based tutoring systems are often grammatically and semantically incomplete and additional information (e.g., dialogue history) is needed to better assess their correctness. In that, we have proposed augmenting semantic similarity based models with, for example, knowledge level of the student and question difficulty and jointly modeled their complex interactions using Probabilistic Soft Logic (PSL). The results of the proposed PSL models to infer the correctness of the given answer on DT-Grade dataset show the more than 7% improvement on accuracy over the results obtained using a semantic similarity model.

Keywords

Tutoring System, Answer Assessment, Probabilistic Soft Logic

1. INTRODUCTION

Open ended answers are responses produced by students to questions, e.g. in a test or in the middle of a tutorial dialogue. Such answers are very different from answers to multiple choice questions where students just choose one or more options from the given choices and they are more easier to evaluate than open ended answers. In conversational Intelligent Tutoring Systems (ITSs; [18, 14]), the systems should be able to assess the students' responses in order to provide them appropriate feedback and to plan the subsequent part of the dialogue.

The true understanding of student answers is intractable as it requires collecting and doing reasoning over a huge knowledge, including the linguistic knowledge, domain knowledge, and world knowledge. As a practical alternative, semantic similarity methods are applied [5, 10, 15]. In this approach, systems assess student responses by measuring how much

of the targeted concept is present in the student answer. Accordingly, the subject matter experts create target (or reference) answers to the questions that students will be prompted to answer and the system assesses how much of the targeted concept is present in the student answer by measuring the semantic similarity between student's answer with reference answer.

The meaning of the reference answer is known because they are created by subject matter experts. The high similarity between student answer with reference answer indicates that the answer is correct. Otherwise, the answer is partially correct, or incorrect. This approach has been widely used in understanding student responses in tutoring systems and in automatic answer assessment systems in general (see Section 2). It is fast, does not require too much of information, and has been often found to be effective.

However, the implied assumption in similarity based answer assessment approach is that the student answer and the reference answer are self contained (i.e., grammatically and semantically complete). But student responses in conversational tutoring systems vary a lot as illustrated in Table 1. The meanings of students' responses often depend on the dialogue context and problem/task description. For example, students frequently use pronouns, such as *they*, *he*, *she*, and *it*, in their response to tutor's questions or other prompts. In an analysis of tutorial conversation logs, Niraula *et al.*[13] found that 68% of the pronouns used by students were referring to entities in the previous utterances or in the problem description. In addition to anaphora, complex coreferences are also employed by students.

Furthermore, in tutorial dialogues students react often with very short answers which are easily interpreted by human tutors as the dialogue context offers support to fill-in the blanks or untold parts. Such elliptical utterances are common in conversations even when the speakers are instructed to produce more syntactically and semantically complete utterances [4]. By analyzing 790 student responses given to DeepTutor tutoring system [14], we have found that about 25% of the times even human needed additional information, such as the dialogue history in order to properly assess them [2].

As illustrated in Table 1, the student answers may vary greatly. For instance, answer A1 is elliptical. The *bug* in A2 is referring to the mosquito and *they* in A3 is referring

Rajendra Banjade and Vasile Rus "Assessing Student Response in Tutorial Dialogue Context using Probabilistic Soft Logic" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 258 - 263

Table 1: Some student answers to the given question asked at some point during interactions with DeepTutor.

Problem description: A car windshield collides with a mosquito, squashing it.
Tutor question: How do the amounts of the force exerted on the windshield by the mosquito and the force exerted on the mosquito by the windshield compare?
Reference answer: The force exerted by the windshield on the mosquito and the force exerted by the mosquito on the windshield are equal and opposite.
Student answers:
A1. <i>Equal</i>
A2. <i>The force of the bug hitting the window is much less than the force that the window exerts on the bug</i>
A3. <i>they are equal and opposite in direction</i>
A4. <i>equal and opposite</i>

to the amount of forces exerted to each other. Due to such variations in the answers, the semantic similarity methods alone can have issues in properly assessing those answers. For instance, the similarity between answer *A1* and the reference answer will be very low.

In this paper, we present Probabilistic Soft Logic (PSL; [3]) model for improving automatic assessment of open-ended answers in conversational ITS by augmenting the semantic similarity model with additional information, such as question difficulty and the knowledge level of the student. For instance, a high knowledge student answering many of the difficult questions correctly will probably answer the current question correctly. The proposed method allows us to model the complex interactions between the stochastic variables, such as student's knowledge level, question difficulty and the correctness of the student answer. In specific, the proposed PSL model which works on probabilistic reasoning framework allows us to concisely express our knowledge in First Order Predicate Logic (FOPL) rules and to provide the extent of our belief on such knowledge as weights. The inference is done over Probabilistic Graphical Model (PGM).

We evaluated our models on a dataset consisting of 790 responses collected during DeepTutor experiments and annotated for their correctness. The results show that augmenting the similarity model with question difficulty and knowledge level of the student improved the accuracy of our answer assessment model by about 8% when compared to results obtained using only the semantic similarity information.

2. RELATED WORK

Our work is more focused on assessing student responses in conversational tutoring systems. But most of the existing work has been performed on standard test taking environment (e.g., assignment checking). In this section, we briefly discuss approaches for constructed answer assessment where the student answers are short (one to just few lines) and the reference answers are available to compare with.

Martin *et al.* [9] proposed an assessment system OLAE using Bayesian nets. Latent Semantic Analysis (LSA; [8]) and

machine translation evaluation methods are also applied for answer grading. LSA method was also used in AutoTutor system [7].

Various researches show that the similarity based methods can be potentially used in the answer grading tasks [10, 15, 11]. In fact, a Semantic Evaluation (SemEval) shared task called Joint Student Response Analysis and 8th Recognizing Textual Entailment Challenge was organized in 2013 [5] to promote and streamline research in this area and almost all of the participating teams applied semantic similarity and textual entailment techniques.

Although various results show that the similarity based methods can be used in answer grading tasks, their implied assumption is that the text available are standard texts with noise filtered. Our work is focused on using naturally occurring texts from conversational tutoring systems where various linguistic phenomena are present, such as coreferences and ellipsis as discussed in Section 1. We also augment the semantic similarity based model using additional knowledge.

Furthermore, various datasets have been published over the years [12, 10, 5, 17]. But dataset from conversational systems with additional information (e.g., previous utterance, problem description, knowledge level of the student, question difficulty) are very limited. We annotated 790 student responses collected during an experiment with DeepTutor [14]. The dataset is made available for research purpose [2].

3. DATASET

We created the DT-Grade dataset [2] by extracting student answers from logged tutorial interactions between 36 junior level college students and the DeepTutor system [14]. During the interactions, each student solved 9 conceptual physics problems and the interactions were in the form of purely natural language dialogues, i.e., with no mathematical expressions and special symbols. We selected 790 answers for the annotation. We chose the more difficult ones (by observing responses from some students, the nature of the question, and so on) such that the similarity based models alone will have difficulty judging those answers.

Table 2: Summary of DT-Grade dataset.

Label	Count
All	790
Correct	319 (40.379%)
Correct but incomplete	292 (36.962%)
Incorrect	179 (22.658%)

Each instance contains the following information: (a) problem description (describes the scenario or context), (b) tutor question, (c) student answer in its natural form (i.e., without correcting spelling errors and grammatical errors), (d) list of reference answers for the question and has been assigned one of the following labels.

1. **Correct:** Answer is fully correct in the context. Extra information, if any, in the answer is not contradicting with the answer.
2. **Correct-but-incomplete:** Whatever the student provided is correct but something is missing, i.e. it is not complete. If the answer contains some incorrect part also, the answer is treated as incorrect.
3. **Incorrect:** Student answer is incorrect.

The dataset and further details about the collection and annotation of it can be found at [2].

4. PROBABILISTIC SOFT LOGIC MODELS

4.1 Background

Probabilistic Soft Logic (PSL; [3]) is an approach to combining knowledge in the form of first-order logic rules and probability in a single representation. It forms Probabilistic Graphical Models (PGM) which allow us to efficiently handle uncertainty and first-order logic allows us to compactly represent the knowledge. Furthermore, it allows us to jointly model the complex interactions among stochastic variables. For example, voting decision of friends has some influence on each other. Similarly, in answer assessment, a high knowledge student giving correct answers to the difficult questions will probably answer another difficult or easy question correctly and we can model such knowledge in a PSL model. On the other hand, typical machine learning algorithms assume that the data bear *i.i.d.* properties.

First-Order Knowledge Base. A first-order knowledge base (KB) is a set of formulas in first order logic [6]. Formulas are constructed using symbols: *constants*, *variables*, *predicates*, and *functions*. Constant represents an object (e.g., John). Functions represent mappings from tuples of objects to objects (e.g., *FatherOf*). Predicate represents relations among objects (e.g., *Friends*) or attributes of objects (e.g., *Smokes*). The formulas are typically written in clausal form (also known as conjunctive normal form (CNF)). For example,

$$Friends(x, y) \wedge Friends(y, z) \rightarrow Friends(x, z)$$

PSL Program. A PSL program consists of rules along with relative weights associated with them and the data (or

observations). The weights in the following example rules are assigned quite arbitrarily but they can be learned from the data which we discuss later.

$$5.0 : Friends(x, y) \wedge Friends(y, z) \rightarrow Friends(x, z)$$

$$2.0 : Friends(x, y) \wedge Colleague(y, z) \rightarrow Friends(x, z)$$

The rules are grounded using observations, i.e., each variable in the rules is assigned to all possible values in the observed data. For example, if there are three people: Joe, Bob, and Lili, then a grounded rule would look like,

$$5.0 : Friends(Joe, Bob) \wedge Friends(Bob, Lili) \rightarrow Friends(Joe, Lili)$$

Predicates in PSL program can have truth values in the range of [0 1], i.e. they are soft. For example, if it is not sure about the friendship of Joe and Bob but there is some possibility, then this uncertainty can be defined as a truth value in the range of 0 to 1. This is different from Markov Logic Network (MLN) where the predicates can have truth values either true or false (i.e., constraints in MLN are harder than PSL).

Prior Knowledge. The prior knowledge can also be encoded as rules in the PSL program. In our hypothetical example, let's assume that people who are neither friends of friends nor friends of colleagues can still be friends but the chances are very low. This can be expressed in the PSL program as illustrated below. It should be noted that the weight to our prior is very low as our belief is that any two persons being friends to each other (given no additional information) is possible but very less likely.

$$0.0001 : Friends(x, z)$$

As mentioned, the weights to the rules can be learned from the data itself. We discuss on this later. Next, we discuss some of the variables, predicates and rules we used in our PSL program (or model).

4.2 Model

Variables. Our model has two variables (*s* and *a*) and by convention, the variables are represented by lower case letters.

s - Student id, *a* - Answer id (or just id) which uniquely identifies an instance in the dataset. It should be noted that the question belonging to *a* may be same as that of some other answer id *b* because the same set of problems were attempted by multiple students.

Predicates. Following are the predicates used in our model.

- *SimilarityHigh(a)* $\in \{0, 1\}$ - similarity of answer *a* with corresponding reference answer is high
- *SimilarityMedium(a)* $\in \{0, 1\}$ -similarity of answer *a* with corresponding reference answer is medium

- $SimilarityLow(a) \in \{0,1\}$ - similarity of answer a with corresponding reference answer is low
- $PriorKHigh(s) \in \{0,1\}$ - prior knowledge of the student s is high
- $PriorKMedium(s) \in \{0,1\}$ - prior knowledge of the student s is medium
- $PriorKLow(s) \in \{0,1\}$ - prior knowledge of the student s is low
- $QDifficultyHigh(a) \in [0,1]$ - question difficulty is high (fraction of students who answered the question corresponding to a incorrectly)
- $QDifficultyMedium(a) \in [0,1]$ - question difficulty is medium (fraction of students who answered the question corresponding to a correctly but incompletely)
- $QDifficultyLow(a) \in [0,1]$ - question difficulty is low (fraction of students who answered the question corresponding to a correctly)
- $AttemptedBySameStudent(a,b) \in \{0,1\}$ - whether a and b were attempted by the same student
- $Correct(a) \in [0,1]$ - the truth value of answer a being correct
- $CorrectButIncomplete(a) \in [0,1]$ - the truth value of answer a being correct but incomplete
- $Incorrect(a) \in [0,1]$ - the truth value of answer a being incorrect

We have created three predicates for semantic similarity and for prior knowledge to avoid biases in assigning weights in some rules. For example, if we have rules 3.0 : $Similarity(a) \rightarrow Correct(a)$ and 2.0 : $Similarity(a) \rightarrow Incorrect(a)$, then low value of similarity score will still favor the first rule.

Rules and Priors. We present few rules with quite arbitrary weights. We learn the weights for those rules from the data which we present later in this section. The priors (starting with negation symbol \sim) specify the possibilities of being false. It should be noted that the weights are relative to each other and do not have to sum up to 1.

2.0 : $SimilarityHigh(a) \wedge QdifficultyLow(a) \rightarrow Correct(a)$
 3.0 : $SimilarityLow(a) \rightarrow Incorrect(a)$

...

0.002 : $\sim Correct(a)$

0.004 : $\sim CorrectButIncomplete(a)$

0.003 : $\sim Incorrect(a)$

4.3 Data

We used DT-Grade dataset described in Table 2. It includes responses provided by 36 students and we also had pretest scores for them. The pretest was a multiple-choice test which consisted of 39 questions.

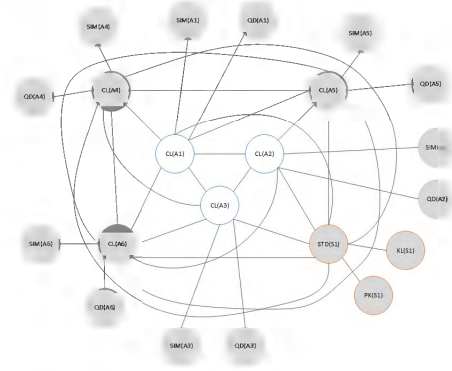

Figure 1: An illustration of a grounded probabilistic graphical network for a student. The shaded nodes are evidence nodes and non-shaded nodes are query nodes. CL - Correctness label, QD - Question difficulty, STD - Student, KL - Knowledge level, SIM - Similarity.

4.4 Grounding

During grounding phase, all the variables in the rules are substituted with possible values from the observations (i.e., data). Figure 1 illustrates an example of a grounded graphical network for a student's data but the graph can grow very large. For instance, the nodes corresponding to correctness labels of each answer are actually 3 (*Correct*, *CorrectButIncomplete*, and *Incorrect*) but in the graph they are represented by a single node *CL*. Similarly, the question difficulty *QD* has three values (high, medium, and low) and each one is actually represented by a separate node. Also, each student has attempted around 20 questions in average (counting those in the DT-Grade dataset only) which makes the graph bigger than what is shown in the figure. We discuss on the scale of the network in Weight Learning section.

The shaded nodes in the graph are observed nodes which we call **evidence**, whereas the light nodes are **query** nodes. During inference, the truth values of the query nodes are predicted jointly based on the evidence.

The similarity between student answer and the corresponding reference answer was calculated using optimal word alignment based method which has performed very well in general. We used the methods implemented in SEMILAR library [16]. We then grouped the similarity scores into high (score > 0.5), medium ($0.5 \geq \text{score} > 0.35$), and low (≤ 0.35) using empirically chosen threshold values. Similarly, we grouped the prior knowledge of the students into high (> 0.8), medium ($0.8 \geq \text{score} > 0.5$), and low (≤ 0.5) based on their pretest scores.

We calculated the question difficulty (high, medium, and low) as discussed in Section 4.2 (predicate definitions related to question difficulty). However, for question difficulty we have used soft values. In specific, each question has soft value (in $[0,1]$) for each of the difficulty levels: high, medium, and low. But for the difficult question, for example, the truth value of the predicate $QDifficultyHigh(a)$ will have higher value than the truth value of the predicates corresponding to other difficulty levels (medium, and low).

Figure 2: Results of different Probabilistic Soft Logic models on DT-Grade dataset. The models ending with *P* used the prior information learned using Logistic Regression (LR) models.

4.5 Weight Learning for PSL Rules

Laying out the internal details, the PSL rules' weight learning process is similar to typical supervised model learning process. We provide the ground truth (human annotated correctness label of the given answer) for the query predicate (which corresponds to a node in the grounded network graph). For each answer, there will be three query predicates one for each of the three labels. Since the labels are mutually exclusive, only one of them is set to 1.0 while other two will be set to 0.0. As we discussed earlier, the grounded network can become very large depending on the set of rules and the size of the dataset used to ground the rules.

Also, the same node cannot be a query node as well as evidence node at the same time. Therefore, we have replicated each student's data several times and renamed their ids such that we can make each answer in the original set (though renamed) a query at one time while using it as an evidence when other nodes are query nodes. This is important for us in both training (i.e., learning rules' weights) and evaluation phase because the dataset we used is comparatively small. For instance, if we make one answer for each student a query and keep others as evidence, then we will have only 36 records for the weight learning as well as for the evaluation. But making each node a query node at least once, we have the full dataset which is several times bigger than the aforementioned size and we can also evaluate our model using the full dataset (for example, by using leave-one-out approach). In another words, this process allows us to utilize the full set of data.

Just to get a sense of the scale of the graph, we assume that each student's data is replicated 5 times. Then the size of the graph (by taking the dominant term only) will be $(5 * 790) * (5 * 790) \sim 15$ million. Weight learning in such a huge probabilistic graphical model is impossible at least in our experimental settings. Therefore, we have pruned some rules that rapidly increase the size of the graph (e.g. the rules of the type: if answer to *a* is correct, then answer to *b* is also correct for the given student) and the resulting graph had about 200,000 nodes, on which we have managed

to learn the weights for the rules.

For those rules which rapidly increase the size of the network with increasing size of the data, we have learned the weights for each student and estimated the weights of the rules using weights learned at student level which is the sub-optimal solution. For each student, the average size graph had only few thousand nodes.

5. RESULTS

Including semantic similarity and additional information, we built several PSL models. For the experiments, we used the PSL tool¹ developed at University of Maryland, College Park. The tool uses Hinge-Loss Markov Random Fields (HL-MRFs) for inference and weight learning [1]. We set the number of iterations to be performed by the optimizer to 50,000.

By assuming that the performance of a student is independent of others, we refactored the graph into subgraphs one for each student and took the leave-one-student-out approach for PSL rules' weight learning and evaluation. As discussed in Section 4.5, we learned the weights for the rules from 35 students at a time (except for few rules for which weights were estimated using weights learned student-wise) and applied to the leave out student. Performing inference in such smaller graphs is computationally very efficient (takes few seconds for each student when run in a normal workstation). Also, the question difficulty was calculated based on training data only, i.e. using 35 students' data at a time.

Once inference is complete, i.e. the truth values for *Correct*, *CorrectButIncomplete*, and *Incorrect* predicates are assigned for each query answer. We then chose the correctness label corresponding to the highest truth value among those three. It should be noted that the truth value for each of them was in the interval $[0, 1]$ but their sum does not have to be 1.0. Then, we calculated the accuracy and F1 scores. The results of our various models are presented in Figure 2.

The baseline system is the majority class classifier, i.e. which labels each answer as correct. The accuracy of this baseline model was 40.379% which is equivalent to the percentage of correct answers in the dataset. *SIM* model used the similarity information only. It obtained 9% improvement over the baseline. As mentioned earlier, the DT-Grade dataset was developed by selecting the difficult cases, particularly difficult to judge by only comparing the student answer with the reference answer. Therefore, we consider 9% improvement in accuracy over baseline results as a notable improvement.

We then augmented the model using knowledge level (*KL*) of the student and question difficulty (*QD*). The *KL* includes the prior knowledge of the student which was assessed using multiple choice questions. The results were improved after adding question difficulty and knowledge level separately. Furthermore, when combined together our model achieved 53.417% accuracy which is above 4% improvement over results obtained using similarity information only.

In an another experiment, we used the priors learned using

¹<http://psl.linqs.org/>

Logistic Regression (LR). In specific, we obtained the probabilities (precisions) of any answer being *Correct*, *CorrectButIncomplete*, and *Incorrect* based on correctness predictions made by LR model when the given set of rules were used as features and used them in our PSL models as priors (model names ending *_P*). Since the priors in PSL models needed to be in negated form, we deducted each probabilities learned from LR from 1.0 and used the resulting values as priors. This has improved the results by about 5% in *SIM_QD* model and about 3% in *SIM_QD_KL* model. The results are above 7% when compared to *SIM* model. These results are also better when compared to the results of LR model itself. This shows that the LR model which is very different from PSL can complement the PSL model.

We learned priors using LR model only for *SIM_QD*. The *SIM_KL* included pretest scores as well as rules of the type: if answer to *a* is correct, then answer to *b* is also correct for the given student. Such rules that capture the relational dependencies are not easily modeled in Logistic Regression. Furthermore, the results of *SIM_QD_KL_P* is slightly less than *SIM_QD_P*. It seems that the concordance between the weights of the PSL rules and the priors learned separately may not be perfect in some cases.

6. CONCLUSION

We presented joint learning models using Probabilistic Soft Logic (PSL) for improving the assessment of open-ended student responses in conversational tutoring systems where the student responses can vary a lot. Specifically, our models augmented semantic similarity information with non-linguistic knowledge (student's knowledge level and question difficulty) and improved the accuracy of the assessment model when evaluated with DT-Grade dataset. The accuracy of our model using informed priors was up to 57.215%, which is more than 7% improvement over the results of semantic similarity based models. In the future, we intend to add additional information in the model and improve on PSL rules' weight learning by clustering students' data.

ABSTRACT

Simplified categorizations have often led to college students being labeled as full-time or part-time students. However, at many universities student enrollment patterns can be much more complicated, as it is not uncommon for students to alternate between full-time and part-time enrollment each semester based on finances, scheduling, or family needs. While prior research has established that full-time students maintain better outcomes than their part-time counterparts, little study has examined the impact of mixed enrollment patterns on academic outcomes. In this paper, we apply a Hidden Markov Model to identify students' enrollment strategies according to three different categories: part-time, full-time, and mixed enrollment. According to the enrollment classification we investigate and compare the academic performance outcomes of each group. Analysis of data collected from the University of Central Florida from 2008 to 2017 indicates that mixed enrollment students are closer in performance to full-time students, than part-time students. More importantly, during their part-time semesters, mixed-enrollment students significantly outperform part-time students. Such a finding suggests that increased engagement through the occasional full-time enrollment leads to better overall outcomes.

Keywords

Hidden Markov model, student enrollment mode, academic outcomes

1. INTRODUCTION

In practice, either through choice or necessity [10, 15, 5, 11, 13], students engage in a variety of enrollment patterns over their academic career that includes full-time and part-time enrollment, or halting [13]. Based on a survey conducted at 253 academic institutions, only 18% of students maintain full-time status during all semesters they are enrolled, while 29% of students maintain part-time enrollment over their whole academic career. Meanwhile, the majority of

students, 59%, change their enrollment status between part-time and full-time at least once during their studies [1].

To date, part-time enrollment status has been indicated as risk-factor to student success. Feldman [8] shows that on average, at the end of the first academic year, full-time college students have higher retention rates and GPAs when compared to the part-time students. In another study, Pelkey [14] analyzed how race, age, enrollment status, GPA and financial aid can impact a student's persistence. Their analysis indicated that GPA and enrollment status, have the highest impact on persistence at college. Not only is enrollment status a factor but so is course-load, as demonstrated in [6], students with more credits during their first semester are more likely to complete their credits and degrees.

Despite it's perceived importance to student success there is no clear definition of what it means to be a *part-time* student or *full-time* student outside the ephemeral academic label. Given that the majority of students alternate between both enrollment statuses, it appears to be overly simplistic to group students together for analysis based on their enrollment status during a single semester; there is likely value in understanding more complex enrollment dynamics, and it's potential value in understanding student outcome. This assertion is supported by a 2015 nation-wide study indicating that student success can be found through mixed enrollment strategies [16] – the authors report that non-first-time-in-college students that attend college utilizing a combination of part-time and full-time enrollment are less likely to drop out and more likely to complete degrees when compared to full-time students.

In this study, we seek to find a more comprehensive means of identifying and clustering students with regards to their enrollment strategy (e.g. part-time, full-time, etc). Unlike a single-period model in which the students' strategy is equivalent to the observed student status (part-time or full-time), we make use of a multi-period dynamic approach using the Hidden Markov Models. Through application of the model we are able to provide a richer understanding of enrollment strategies, by extending our traditional notions to include not only full-time and part-time enrollment strategies, but also a mixed enrollment strategy. Students who use a mixed enrollment strategy regularly alternate between full-time and part-time status. After categorizing students into three groups of full-time, part-time and mixed enrollment strategy, we examine the student outcomes such as

2. PROBLEM STATEMENT

We consider the problem of classifying students according to their enrollment strategy as opposed to their enrollment status during any given semester. For many students the distinction between enrollment strategy and actual enrollment is minor. At the University of Central Florida a students is considered as full time student in a given semester if he or she takes more than 12 credits in that semester. For approximately 35% of the student-body at the University of Central Florida, their enrollment status is consistently full-time throughout their academic career, meaning they employ a strategy of enrolling full-time. In contrast, the case for so-called *part-time* students it is not so clear. In any given semester, about 30% of enrollments are part-time, and yet only 7% of students consistently enroll part-time over their academic career. Enrolling part-time in any given semester is not equivalent to the strategy of consistently enrolling part-time. It follows that just because a student enrolls in a single semester part-time, that does not mean they bear similarity to student's who consistently enroll part-time.

The goal of this paper is to recognize and report the distinction between a student's enrollment strategy and enrollment status, and to find a more meaningful way to classify students over their academic career. More specifically, this paper develops a model that takes as its input a sequence of enrollment statuses and returns a sequence of estimated strategies applied over the same time-frame. In recognition that students apply a greater diversity of strategies then just a full-time enrollment strategy (FES) or part-time enrollment strategy (PES), we introduce the notion of a mixed enrollment strategy (MES). For a mixed enrollment strategy, students alternate between part-time and full-time enrollments. Table 1 provides examples of the enrollment status of four different students over their academic career along with the corresponding enrollment strategies. For example, enrollment strategies for student number 1 through number 3 are FES, MES, and PES respectively.

3. METHODOLOGY

In this study, we generate and apply a Hidden Markov Model (HMM) to identify students' enrollment strategy, and to characterize the impact of enrollment strategy on student outcomes. The use of HMM is not new to educational data mining and modeling. Previously it have been used to investigate students' sequential behaviors, decision-making, and performance [2, 3, 4, 9, 12, 7]. As an example Falakmasir et al. [7], classified students into low-performing and high-performing groups and applied and trained two hidden Markov models for each group separately. For each HMM,

Figure 1: Representation of a simple Hidden Markov Model

they used forward algorithms to compute log-likelihoods for the observation sequences. They continued by applying a linear regression model to explain the difference between the computed log-likelihoods so as to predict post-test scores for the low-performing and high-performing students. Other papers have used HMMs in order to model sequential student behavior. Beal et al [4] colleagues modeled high school students' actions and behaviors using HMMs. By estimating HMM parameters with the Baum-Welch algorithm for each student, the authors clustered the students based on the individual transition matrices to assess differences in behavior and achievement of different clusters.

As depicted in Figure 1, similar to ordinary Markov Models, a HMM represents the dynamics of a system as it moves between operating states or modes (e.g. Modes 1, 2, and 3 in the figure). When operating within a state or mode, the system generates state-related output O_i at each time-step. Unlike Markov Models, in the case of the HMM problem the states are not always directly observable, and as such they can only be estimated by observing a sequence of outputs. For the problem under consideration here, the hidden state corresponds to the enrollment strategy of a student (e.g. full-time enrollment strategy, mixed enrollment strategy, part-time enrollment strategy), and the observations refer to the actualized enrollment in any given semester in the student academic history.

To give a formal definition of Hidden Markov models, we must begin with the following notations: $Q = \{q_1, q_2, \dots, q_N\}$ represents the set of N possible states in the system; $A = [a_{i,j}] \in \mathcal{R}^{N \times N}$ is a transition matrix, where each $a_{i,j}$ denotes the probability of transitioning from state i to j at any given time-step; $O = o_1, o_2, \dots, o_T$ represents a sequence of observations of length T , each drawn from the set of M possible observations $V = \{v_1, v_2, \dots, v_M\}$; and π represents the distribution of the initial state the system begins in. When a system is operating in a specific state q_i , the output o_t at any given time t is generated according to a unique probability distribution denoted as $B = b_i(o_t)$, the emission probability.

In order to generate a HMM to represent student enrollment strategies, we must learn the optimal model parameters $\lambda = (A, B, \pi)$ that reproduce known observations. The

process of learning λ is based on the Baum-Welch algorithm, which is an iterative process that requires calculating the likelihood of any sequence of observations given λ , and decoding relationships between observations and hidden variables. As the model is iteratively updated, the likelihood calculations and the decoding is updated.

4. STUDENT DATA RECORDS

The study presented in this paper makes use of processed undergraduate student records collected from the University of Central Florida, a large public university in the southeast United States, between the years of 2008 to 2017. The total data-set amounts to approximately 170000 records. The data set contains a wide variety of information about students at UCF, including but not limited to: (1) demographic information, (2) admission information for students who have been admitted and enrolled, (3) degrees awarded (for bachelor level), (4) courses taken by student at UCF, and (5) family income. Some of the demographic information along with the fraction of students who enroll as full-time and part-time, and admission type (FTIC and transfer) are provided in Tables 2 through 5.

Table 2: Students gender distribution at UCF over 10 years

	Females	Males
Percentage	56%	44%

Table 3: Students ethnicity distribution at UCF over 10 years

	White	Hispanic	African-Am.	Other ¹
Percentage	55%	24%	11%	10%

Table 4: Students admission type distribution at UCF over 10 years

	First-Time-in-College	Transfer
Percentage	41%	59%

The processed student data includes a unique identifier, along with the student's observed academic load for semester they enrolled. Synthetic examples are shown in Table 1. For each student their enrollment sequence is ordered from their first observed enrollment to their last observed enrollment without making note of the semester or year. The data set includes both partial, halted, and graduated enrollment sequences within the indicated 10 years date-range. For the purposes of this study we restrict the problem to enrollment during Fall and Spring semesters, as such information regarding Summer enrollment is excluded when constructing the HMM. It is worth noting that the data-set includes both first-time-in-college students and transfer students.

¹The other category includes American-Indian, Asian, Native Hawaiian, and Multi-racial ethnicity

Table 5: Enrollment type distribution for different semesters at UCF over 10 years

Semester	Full-time	Part-time
Fall	73%	27%
Spring	71%	29%
Summer	10%	90%

5. APPLYING HMM TO STUDENT DATA

In applying the HMM model to our problem, we begin by identifying the set of hidden states corresponding to three different enrollment strategies: full-time enrollment strategy (FES), part-time enrollment strategy (PES), and mixed enrollment strategy (MES). The probability a student changes his or her enrollment strategy from one semester to the next is represented using a probability transition matrix A . While the probability of observing an enrollment status while using a specific enrollment strategy is given by the emission matrix B . Finally, π is the probability distribution over the students enrollment strategy during their first enrolled semester.

Beginning with an initial guess for A , B , and π , the Baum-Welch algorithm is applied to estimate the true model parameter set (λ). Converging after 20 iterations, the following values for A , B , and π are generated:

$$A = \begin{bmatrix} 0.898 & 0.05 & 0.052 \\ 0.168 & 0.74 & 0.092 \\ 0.007 & 0.12 & 0.873 \end{bmatrix} \quad (1)$$

$$B = \begin{bmatrix} 0.974 & 0.026 \\ 0.611 & 0.389 \\ 0.061 & 0.939 \end{bmatrix} \quad (2)$$

$$\pi = [0.718 \quad 0.113 \quad 0.169] \quad (3)$$

For any two subsequent semesters t and $t + 1$, the rows in the transition matrix A correspond to states FES, MES and PES at semester t , while the columns correspond to states FES, MES and PES at semester $t + 1$. Based on the estimated transition matrix A , most of the students maintain their enrollment strategy with high probabilities from one semester to the next. Reading the diagonal of the matrix, with .898 probability a student employing a FES will continue employing a FES, similarly .74 for PES and .873 for MES. This indicates that most students maintain a static enrollment strategy, even if it is a mixed one.

For emission matrix B , each rows correspond to the probability of full-time and part-time enrollment status in a semester for a given enrollment strategy. Result indicate that students employing FES register full-time with probability 0.974 and as part-time with probability 0.026. While students employing a PES only register full-time with probability 0.061 versus part-time at 0.939. Most interesting are students with MES, as their full-time and part-time enrollment is split between 0.611 and 0.389. The, initial probabilities matrix π indicates that most of the undergraduate students start their first semester with full-time enrollment strategy (with probability 0.718). Moreover, the probability of being at PES

Figure 2: Distribution students' enrollment strategy

and MES at the first semester are 0.169 and 0.113 respectively.

6. ANALYSIS

After estimating model parameters, the next step is to find the strategies (hidden states) for each student in the data set at each semester with the Viterbi algorithm. Based on the estimated hidden states, students are classified into four groups, three of which corresponds to the students who maintain a consistent strategy of FES, PES or MES during their education. The last group corresponds to students who employee a combination of FES, MES and PES over their academic career. Figure 2 shows how students are distributed among these four groups.

Based on Figure 2, most of the students maintain their enrollment strategy during their educational career (Sum of green, red and yellow slices, approx. 73.4%). The most prevalent consistent enrollment strategy is FES, followed by PES and MES groups. For those students that change strategies at some point in the academic career, 73%, change from FES to PES, and 15% move from PES to MES. For virtually all cases of FES to PES, the majority of students adjust their enrollment strategy during their last two semesters. Anecdotally, it appears this shift is due to course scheduling inefficiencies and early entrance into the work place through co-op placements.

Furthermore, Table 6 represents percentage of male and female students for different enrollment strategies. The percentage of female students in FES, MES, and PES groups are 55%, 54%, and 55% respectively, which emphasizes that students enrollment strategy is independent of students gender. Table 7 indicating how students with different ethnicity are distributed among the three enrollment strategy groups. As the table shows, the ratio of students with white and Hispanic ethnicity in FES group are different to MES and PES groups. Hypothesis *t*-tests are conducted to assess statistical significance of these differences. For FES and PES groups, the *p*-value is close to 0, implying the difference in the ratios are statistically considerable. However, other complicating factors have not been considered.

Clustering of the students based on enrollment strategy (FES, PES, MES), a number of descriptive statistics are calculated.

Table 6: Female and male ratios for students with different enrollment strategies

Strategy	Female	Male	Number of students
FES	55%	45%	74571
MES	54%	46%	5321
PES	55%	45%	20466

Table 7: Ethnicity ratios for students with different enrollment strategies

Strategy	White	Hispanic	African-Am	Other
FES	56%	22%	12%	10%
MES	50%	27%	13%	10%
PES	50%	27%	13%	10%

They include average cumulative GPA, family income, 6-year graduation rate, and halting. The average GPA for each strategy cluster is shown in Figure 3. Results show that the FES group has the highest average GPA. The lowest GPA corresponds to the PES group, while the MES group's GPA lies in between.

Figure 3: Average GPA for different enrollment strategies

To assess if the average GPA for each group are statistically different from the other groups, statistical hypothesis *t*-tests are conducted. The result shows that the *p*-values for all the hypothesis tests are nearly to 0, indicating that the average GPA for each group is statistically different from others. The results are summarized in Table 8.

Furthermore, inside each strategy cluster, the average GPA during full-time and part-time semesters are calculated. As indicated in Figure 4, for the FES group the average GPA for full-time and part-time semesters are 3.1 and 2.8. This indicates that students employing a full-time enrollment strategy, tend not to perform as well when registering part-time. The same conclusion is observed for students in the PES group, that is, student utilizing a part-time enrollment strategy perform better when they enroll full-time². Of interest

²For both FES and PES, comparison of GPAs between full-time and part-time semesters through difference of means statistical tests rejects the null hypothesis that the means are equal, $P = .001 < .05$

Table 8: Results for the GPA hypothesis tests

Pair of groups	P-value
FES and PES	0
FES and MES	$6.5e^{-84}$
MES and PES	$1.82e^{-86}$

Table 9: Results for the family income hypothesis tests

Pair of groups	P-value
FES and PES	0.7463
FES and MES	0.6518
MES and PES	0.9603

however, is that for students employing a mixed-enrollment strategy hypothesis tests indicate there is no statistical difference in means between the average GPAs of full-time and part-time semesters; in other words, the semester enrollment status for MES students does not significantly impact their GPAs. While the GPA reductions observed for students employing a full-time enrollment strategy and part-time enrollment strategy appear reasonable, the lack of GPA drop for mix enrollment strategy students is somewhat surprising, it suggests potential value in encouraging part-time students to occasionally enroll full-time.

Next, the impact of the family financial status on student enrollment strategy in each group is compared. As shown in Figure 5 the annual family income for students in all three groups of FES, MES, and PES are close to \$75000. This implies that at UCF, students enrollment strategy is independent to the family income. Kolmogorov-Smirnov (K-S) test is applied in order to assess if there is statistically significant difference in family income distribution for students with different enrollment strategy. As shown in Table 9, the hypothesis test results p-values greater than 0.05 for all three group pairs of indicating no significant difference in annual family income between students with different enrollment strategies.

The next criteria for comparing student performance be-

Figure 4: Average GPA for full-time and part-time semesters based on employed strategy

Figure 5: Annually family income for different enrollment strategies

Figure 6: 6 year graduation rate for students utilizing different enrollment strategies

tween the three different groups is the 6-year graduation rate, summary statistics provided in Figure 6. As the plot shows, PES group has a lower graduation rate (37.3%) when compared to MES and FES groups (with similar graduation rates of approximately 75% and 74%). While the performance difference between PES and FES follows prior studies, it is interesting to note that employing a mix enrollment strategy does not appear to hinder graduation rates³.

7. CONCLUSION

The long-term vision of this research is to help identifying strategies that engender student success. Towards that end, this paper examined different enrollment strategies students apply over their academic career. Through application of Hidden Markov Models on a large student data set, we noted three dominant consistent strategies: full-time enrollment strategy, part-time enrollment strategy, and mixed enrollment strategy. The resulting HMM and its application leads to the conclusion that most of the students have a full-time enrollment strategy. When assessing different features of the three different enrollment strategies, we observe that the average GPA for FES students is the highest, followed by MES and PES students. While graduation rates indicate that students employing the PES are more at risk of

³Difference of proportions fails to find a difference between FES and MES graduation rates, $P=.112 > .05$

not graduating college. Also, financial analysis shows that there is no statistically significant difference between family income distributions for students with different enrollment strategies.

The major contributions of this research is twofold. Firstly, we provide a powerful tool for identifying students enrollment strategy as FES, PES or MES, based on their historical enrollment status. Secondly, our multi-aspect assessments on each group of students, emphasizes the vulnerability of the PES group, while encouraging university to policy-makers identify such students early during their studies and help them shift towards a mixed enrollment strategy by providing them with financial, educational, and social support.

ABSTRACT

How to support students in programming learning has been a great research challenge in the last years. To address this challenge, prior works have mainly focused on proposing solutions based on syntactic analysis to provide students with personalized feedback about their grammatical programming errors and misconceptions. However, syntactic analysis falls short on informing learners how they solve the programming problem, even if one key learning outcome of programming relates to the development of an individual's ability to solve a problem. In this article, we introduce an indicator to analyze beginners' code based on semantic proximity. This indicator adapts an edit distance algorithm (i.e., the Levenshtein distance) to express the proximity of the students' code with the expected solution provided by the teacher, in order to express the learners' capacity to solve the given problem. To process our indicator, we applied machine learning techniques to a dataset from an introductory programming course with a sample of 166 students. The first results are encouraging. On the one hand, the semantic indicator can be used to automatically classify source codes as semantically correct or incorrect in 58% of the cases. On the other hand, the indicator is correlated with teachers' summative evaluations of students' codes. Even if further investigations must be conducted to improve the indicator's accuracy, the results of this study make it possible to use our approach as the foundations for future research in semantic-based intelligent and awareness programming systems.

Programming learning, Semantic analysis, Educational data mining, Edit distance, Levenshtein algorithm

1. INTRODUCTION

Computer literacy is currently booming. In Europe, particularly in Germany and the United Kingdom, profound educational transformations have been initiated since 2016 to promote digital learning in schools and prepare learners

for the acquisition of 21st century skills, which include programming learning. In France, for example, an educational reform of High School curricula that will be operational next year offers a Digital and Computer Science option that includes more than 350 hours of programming learning. This interest in integration of programming learning skills early in the curriculum requires not only prepared teachers, but also technological solutions to support them and their students in their daily practices.

With this purpose, the Technology-Enhanced Learning research community has been interested in designing systems dedicated to support learning of programming, as evidenced by different efforts intended to analyze learners' behaviour [14, 12]. One of the most common approaches in prior works consists in designing systems that analyze learners' programming codes from a syntactical perspective. These systems make a syntactic evaluation of students' codes to detect grammatical errors and provide appropriate and constructive support to learners to avoid misconception errors [15]. However, delivering feedback about syntactical errors falls short on providing meaningful information about how students approach the programming problem. Yet, one of the key learning outcomes of programming relates to the development of an individual's ability to solve a problem [11]. One approach to achieve this goal is to design systems able to analyze source codes from a semantic perspective, i.e., able to show how the problem has been solved. Although there have been some initiatives approaching code evaluation from a semantic perspective [5], works on this line are still scarce and very few solutions have been proposed. Thus, more solutions based on semantic analysis are needed to better understand the potential of this approach in supporting learning of programming.

To advance on semantic analysis-based solutions, this article introduces the design of an indicator revealing the semantic proximity of two distinct source codes in order to express the correctness of a learner's code regarding a given problem, and tackles the following research questions:

Research question 1: How to design a semantic indicator revealing learner's ability to solve a problem?

Research question 2: Is the semantic quality of a learner's production correlated with his/her academic performance?

To answer the first question, we adopt an approach based on the comparison of abstract syntax trees. We adapt the edit distance established by Levenshtein, an algorithm that

Julien Broisin and Clément Hérouard "Design and evaluation of a semantic indicator for automatically supporting programming learning" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 270 - 275

has proven effective in comparing and correcting strings of characters. Then, we propose a machine learning method to determine some of the factors required to process the semantic proximity using source codes produced by 166 students. For the second research question, and with the objective of evaluating the precision of the indicator in relation to human perception, we conduct a set of statistical analysis with source codes gathered from an authentic learning context. In particular, we analyze the correlation between the value of our indicator automatically processed, and the teachers' scores manually assigned to students' source codes.

In the following section we review what current approaches dedicated to automatic source code analysis are currently available in the literature, and highlight a lack of semantic-driven proposals. Then, in Section 3, we present how the semantic indicator was designed; as stated above, the indicator stands on the Levenshtein distance adapted to source codes comparison, and depends on a set of parameters leading to its calculation. Section 4 then introduces the machine learning method we used to assign values to these different parameters, whereas Section 5 describes the dataset used to actually determine the values of the parameters. Section 6 gives the results we obtained, and evaluates the quality of the indicator at two different levels: its capacity to act as a semantic classifier, and its correlation with human perception. Finally, we discuss the results of this study as well as the main conclusions of the work.

2. APPROACHES FOR AUTOMATIC SOURCE CODE ANALYSIS

In the context of programming learning, automatic source code analysis is used to achieve different objectives such as improving feedback provided to learners [7, 9], predicting their performance [1, 16], or monitoring their activities [3].

These automatic analyses are performed by compiling the code [6], by searching for typical errors within a source code [9], or by running unit tests provided by teachers [13]. These various works guide learners in the production of syntactically correct programs, but they do not allow the source code to be evaluated at a semantic level: syntactic evaluation is not sufficient to reflect the relevance of a learner's production regarding a problem given by the teacher.

In the meta-review proposed by Ihantola et al. [8] who studied no less than 118 research articles in the field of educational data mining for programming, the word *semantics* is missing from the paper. Also, a search for the terms "semantic analysis programming" in Google Scholar and Web of Science returns a large number of results, but no scientific articles really deal with semantic analysis of code.

The works we have identified that are close to a semantic analysis are those proposed by Bey et al. [5]. In order to propose an automated assessment of learners' code in a Massive Open Online Course (MOOC), the authors propose to compare the control flow graph matching with the code produced by the learner, with a set of graphs stored in a database and manually assessed by experts [2]. If the learner's graph is recognized among the graphs of the database, then the matching score is returned to the learner; if it is not recognized, then the learner's production is manually assessed by

a human expert to enrich the database of graphs.

The lack of work addressing automatic analysis of source code from a semantic perspective can be explained by the fact that the semantics of a program can not be calculated. Our research try to go beyond this limitation and propose the design of an indicator that reveals the relevance of a source code regarding a given problem.

3. SPECIFICATION OF THE SEMANTIC INDICATOR

Our objective is to design an indicator able to evaluate the distance between two source codes from a semantic perspective and fulfilling the following requirements: (i) teachers should only produce a solution to the problems delivered to students, in contrast, for example, to methods based on unit tests which are time consuming; (ii) the distance should decrease as the student approaches the solution, so that an incomplete script can be evaluated even if it does not fully address the problem posed. Therefore, if the solution of a problem is provided by the teacher, then the distance between this source code and the learners' productions should give insights about their ability to solve the problem.

The field of natural language processing has for a long time studied problems related, for example, to spelling correction where semantics is naturally taken into account [4]. To design our semantic indicator, we studied algorithms capable of processing the edit distance between two sequences of characters, and built our proposal upon the Levenshtein algorithm which has been shown very useful for calculating the distance between two strings of characters.

3.1 Levenshtein distance

The edit distance between two strings of characters, or Levenshtein distance [10], is defined by a cost calculated from the minimum number of operations (i.e., insertion and deletion of a character, and substitution of one character by another) required to move from one string to another. In the case of character strings comparison, the costs associated with each of these operations are all set to 1, but the cost of the substitution of a character by itself which is 0. To apply this algorithm to source code, two challenges must be tackled: (i) the design of a formal representation of the source code in order to make it comparable at a high abstraction level, and (ii) the assignment of a specific cost to each elementary operation according to the importance of the modifications to be made to move from one source code to another. Indeed, substituting two instructions implementing the same functionality should not have the same cost than replacing an instruction with another one characterized by a very different functionality.

3.2 Formal representation of source code

Our proposal for building a formal representation of source code relies on two steps: transformation of the source code as an Abstract Syntax Tree (AST), and transformation of the AST into a string of elementary instructions.

3.2.1 Production of the abstract syntax tree

We have adopted abstract syntax trees to formally represent a source code as they do not represent nodes and branches

that do not affect the semantics of a program. We rely on a parser written in JavaScript that reads a script and returns the matching abstract syntax tree formatted as a JSON object; an example illustrating the conversion of a Bash source code to an AST is given in Figure 1.

With the formal representation proposed above, the measurement of our indicator corresponds to the edit distance between two abstract syntax trees. However, in order to adapt Levenshtein distance to our context, we need to convert the AST generated from the source code into a string of characters; from a terminology point of view, we name *tokens* the characters resulting from the AST transformation process so as not to confuse them with those contained in the source code. Thus, we carry out an in-depth exploration of the AST to create the string of tokens.

3.2.2 Production of the string of tokens

The Bash language, the subject of our study, proposes 17 control structures, each corresponding to a different token. A token can be of the type **Command**, of the type **Assignment**, or of the type **While**, **Do** or **Done** to indicate the beginning, body or end of a loop respectively. Note that the tokens **Command** keep the name of their command and arguments. The transformation of the AST represented in Figure 1 into a string of tokens is illustrated in Figure 2.

The Levenshtein distance between two strings of tokens is therefore characterized by a number of costs, or parameters, matching with the different elementary operations of insertion, deletion and substitution of each token. The 17 tokens of the Bash language lead to the definition of 308 costs: 17+17 costs to create and delete a token, 16x17 costs to substitute one token by another, 1 cost to substitute a token **Command** by another characterized by a different command name, and finally 1 cost to substitute a token **Command** by another characterized by identical names and different arguments. This number of parameters is too high to implement an effective machine learning method, as it decreases the density of tests and makes more difficult the search for "good" values of parameters.

3.3 Reduction of the number of parameters

A first operation to reduce the number of parameters to be trained consists in ignoring the tokens **Until**, **Subshell** and **Pipeline** because the matching control structures do not appear in the dataset used for this study (see Section 5). We also propose to symmetrize the problem by assigning equal costs to the insertion and deletion operations of a token; similarly, the substitution of the token *A* by the token *B* has a cost equal to the substitution of *B* by *A*. This symmetrization makes the distance between the scripts S_1 and S_2 equal to the distance between S_2 and S_1 , and reduces the number of parameters to 107.

Finally, we assume a stronger hypothesis by considering that only certain tokens can replace others. Thus, only the following groups of tokens can substitute each other: {**Command**, **Assignment**}, {**If**, **Case**}, {**Then**, **Else**, **CaseItem**}, and {**For**, **While**}. Indeed, it is possible that a script contains a **Case** where another script uses a **If**, but it is unlikely that a substitution of a **For** by a **If** appears frequently, these two instructions having very different objectives.

These simplifications considerably reduce the number of costs, since 23 parameters must now be calculated. Let us note θ the vector containing these 23 costs. Our indicator, noted $d(S, C, \theta)$, is then defined by the edit distance, under the 23 parameters θ , between the string of tokens representing the script S and the one matching with the script C . The next section introduces the machine learning criterion leading to the optimal values of θ .

4. MACHINE LEARNING METHOD

To train the correct values of the 23 costs of the θ parameter, we define the machine learning criterion $Score(\theta)$ to be minimized such that:

$$Score(\theta) = \frac{\sum_{(S,C) \in Correct} \sqrt{d(S, C, \theta)}}{\sum_{(S,C) \in Incorrect} \sqrt{d(S, C, \theta)}} \quad (1)$$

where *Correct* (resp. *Incorrect*) is the set of pairs composed of the correct (resp. incorrect) scripts of the learning dataset (see next section) and the associated corrections.

The *Score* function is low when the correct scripts are associated to short distances, and the incorrect scripts to long distances. We add the square roots of the distances to reduce the influence of high values.

We can notice a property of the function d :

$$\forall \lambda \in \mathbb{R}_+^*, d(S, C, \lambda \cdot \theta) = \lambda \cdot d(S, C, \theta) \quad (2)$$

Then it is obvious that $Score(\lambda \theta) = Score(\theta)$. This means that the *Score* function is constant on all rays from 0, and that exploring the different costs of the θ parameter, noted θ_i such as $0.01 < \theta_i \leq 1$, is sufficient to find the values of θ_i minimizing *Score*. The dataset built from an authentic learning situation and that was used to determine the θ_i is described in the next section.

5. DATASET FOR CALCULATING COST

The dataset was obtained in an IT department of Higher Education Institute of Technology (HEIT) during an introductory course on Bash programming attended by 166 first year students. Learners discover common commands such as **echo**, **ls**, **read** or **cat**, variable management, as well as some control structures of the Bash language (e.g., **for**, **while**, **if**, **case**). Students then put these concepts into practice during hands-on sessions where they produce Bash scripts to try to solve a series of problems.

The dataset includes the students' scripts produced during five practical sessions of one hour and a half. Each time a student saves the modifications of her Bash script, a copy of the script together with its timestamp and the identifier of the student is saved in a directory to enrich the dataset. Thus, our sample includes 19232 scripts. However, a number of nomenclature errors or file numbering made 18% of these scripts unusable: the dataset is composed of 15794 scripts.

This sample includes, for the same exercise, several scripts produced by the same student. However, machine learning methods are effective when they are based on independent data. We thus only consider, per exercise and per student, the last script produced by the learner because we assume

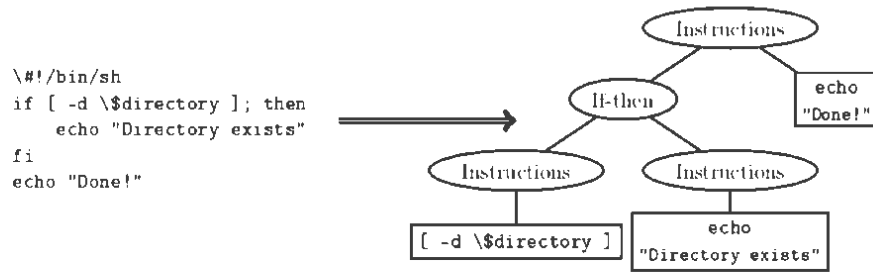

Figure 1: Converting a source code into an abstract syntax tree.

Figure 2: Converting an abstract syntax tree into a string of tokens.

that it is the most complete. This choice allows to obtain an independent dataset, but reduces the sample to 2540 scripts.

Finally, we want to be able to manually classify each script of the dataset into two distinct categories (i.e., *Correct* and *Incorrect*) expressing their semantic accuracy, in order to evaluate the accuracy of our indicator as a semantic classifier (see next section). However, some exercises suggested by the teachers of this course do not allow for a semantic analysis of students' productions. For example, some problems are related to the understanding of the execution of a script provided in the statement, while others have instructions that are too open to assess whether a script represents a solution to the problem. After this classification process, the final sample includes 733 scripts spread over 11 different exercises; 397 scripts are semantically correct, the others being semantically incorrect.

This dataset was randomly divided into a learning dataset whose objective is to identify the values of the θ parameter that minimize the machine learning criterion, and a test dataset that aims at evaluating the relevance of the results obtained during the machine learning phase. These two samples contain the same number of scripts for each exercise, and the proportion of semantically correct and incorrect scripts is preserved. In addition, let us note that a solution was provided by a teacher for each of the exercises.

6. RESULTS AND EVALUATION

6.1 Values of costs

The learning dataset was used to initialize the gradient descent minimization algorithm. The vector minimizing the

Score function, noted $\bar{\theta}$, admits values of 0.01 (i.e., the minimum value we have set) almost everywhere except for three parameters: (1) the creation or deletion of a token **Command**, whose cost is 1; (2) the creation or deletion of a token **If**, whose cost is 0.112; (3) the creation or deletion of a token **Function**, whose cost is 0.022.

At this stage, we have the parameter $\bar{\theta}$ which contains the values of the 23 costs that were obtained by our learning method. The objective of the tests conducted in the following section with the parameter $\bar{\theta}$ on the test dataset is twofold: to study the ability of our indicator to distinguish a semantically correct script from an incorrect script ; to study the correlation between our indicator and manual scores assigned to scripts by teachers.

6.2 Study of prediction

A first approach to assess the relevance of our indicator under the parameter $\bar{\theta}$ is to evaluate its ability to automatically classify a script as correct or incorrect from a semantics point of view. In a first step, we calculate the distance $d(S, C, \bar{\theta})$ between each script S of the test dataset and the correction C of the matching problem, in order to obtain a value of our indicator for each correct and incorrect script.

The next step consists in evaluating the prediction model resulting from the different values of the indicator. To do this, we use the ROC metric, which is widely used to observe the performance of a binary classifier. When the classifier calculates a metric m that is compared to a σ threshold to predict the class, the idea of the ROC curve is to vary σ from 1 to 0 and, for each σ value, plot the false positive rate on

Figure 3: ROC curve of our classifier (in blue) and random bisector (in red).

the abscissa and the true positive rate on the ordinate. The area under the curve (AUC) then indicates the probability that the classifier will place a positive in front of a negative. A classifier that is never wrong has an AUC equal to 1, while a random classifier has an AUC equal to 0.5.

In our study, if $d(S, C, \bar{\theta}) < \sigma$, then the script is classified in the category *Correct*; otherwise it is classified in the category *Incorrect*. The ROC curve in Figure 3 illustrates the ratio of true positives (i.e., fraction of correct scripts that are actually detected as correct by the classifier) according to the ratio of false positives (i.e., fraction of incorrect scripts that are detected as correct by the classifier). The curve is moderately above the bisector, the area under this curve is equal to 0.585. Our classifier is therefore slightly better than a random classifier, but its performance is not very high; we make assumptions to explain these results in Section 7.

6.3 Study of the correlation with human notation

One of the objectives of our indicator is to reflect the learner's progress towards the solution to the problem, which means that its value is assumed to decrease as a script moves towards the solution. We therefore study the correlation between the value of our indicator under the parameter $\bar{\theta}$ for a given script and the matching correction, and the score assigned to this script by a human tutor.

This study is performed using a second dataset obtained after the final exam of the course described in Section 5. Of the 166 students enrolled in this course, 163 participated in the final exam where learners had to produce a script addressing a given problem. A teacher then assigned a score out of 10 to each of the 163 scripts. After eliminating grammatically incorrect scripts, this second dataset comprises 105 scripts.

Figure 4 shows, for each script, the value of the indicator according to the score assigned by the teacher. This graph shows a negative correlation: the (non-linear) Kendall correlation has a value equal to -0.319 (p value less than

Figure 4: Value of our indicator according to score assigned by a human tutor.

$2.7 \cdot 10^{-6}$), the (linear) Pearson correlation having a value of -0.446 (p value equal to $1.9 \cdot 10^{-6}$). We therefore have a correlation between the score given by a human tutor and the value of our indicator. This correlation is not extremely high, but it may be sufficient to automatically estimate a student's progress towards solving a problem.

7. DISCUSSION

Our indicator is able to distinguish a semantically correct script from a semantically incorrect script, but its performance is slightly better than that of a random classifier only. A hypothesis to explain these results stems from the heterogeneous nature of the learning dataset, especially regarding the size of the scripts it contains. Indeed, the distance calculated by our indicator tends to increase with each token of a script. So the longer a script is, the more likely it is that the indicator will return a high value (even if the script approaches the solution), while a short and incorrect script is evaluated with a low value due to the low number of tokens.

The correlation study carried out on the second set of data gives indications about a certain capability of generalization of our approach. Indeed, unlike the test dataset extracted from the first dataset, the set of scripts obtained after the terminal exam corresponds to an exercise that is missing from the learning dataset. Therefore, our method seems to apply to exercises that were not used during the learning phase. However, this correlation is not extremely high, and scripts that are very poorly evaluated by human tutors are assigned a value of our indicator that is almost zero. This can also be explained by the hypothesis formulated above, since almost empty and therefore incorrect scripts are poorly rated by the human teacher, while our indicator returns a low value. Tests should be carried out to investigate how to adjust the algorithm to process the indicator, in particular according to the number of tokens comprised in the script representing the solution to the problem.

Developments have been initiated to return this indicator to learners during the programming activity. A first visualization reflects, as a graphical gauge, the value of the indicator each time a learner executes a script. A second visualization shows the learner's progress in solving the problem from the successive values of the indicator for the same script; it gives the variation of the indicator in the form of a gradient of colors ranging from green (for a short distance) to red

(for a long distance). The student is thus provided with a real time and easy to interpret view of the evolution of the accuracy of his script from a semantic point of view. These tools to support learners will be experimented in the next academic year with a new group of first-year students from HEIT. This experimentation will also make it possible to repeat the work presented in this study using a new dataset, and thus to improve the quality of our indicator.

8. CONCLUSION

In this paper, we conducted a study to design an indicator whose objective is to act as a foundation for intelligent guidance systems and awareness tools intended for both learners and teachers during a practical activity dedicated to learning programming. While a large variety of research is focused on the syntactic quality of the code produced by learners to support these learning activities, our originality lies in studying the semantic quality of the code, i.e., in evaluating the degree to which a program solves a given problem.

Thus, our main contribution relates on the design of an indicator that reflects a learner's ability to solve a problem. To answer the first research question asked in the introduction, we adapted the Levenshtein distance: from two strings of *tokens* representing the abstract syntax tree of the corresponding programs, the indicator returns an estimated value of the edit distance between the two scripts. To train and test this indicator, we used a dataset composed of scripts produced by students in authentic learning situations. The tests revealed that when it comes to differentiating between semantically correct and incorrect scripts, our indicator has slightly better performance than a random classifier. On the other hand, we observed an inverse correlation between the value of the indicator and the score assigned by a human tutor: the higher the human score of a program formulating a solution to a problem, the smaller the distance between that program and the solution of the problem.

These encouraging results suggest the opportunity to develop new models and tools dedicated to the semantic analysis of programming learning. However, many improvements need to be explored to improve the quality of our indicator. In addition to big amount of data required to refine the parameters of our indicator, the generalization of our approach to different programming languages must be checked, as well as the consideration of more complex programs.

ABSTRACT

A student's ability to regulate their thoughts, emotions and behaviors in the face of temptation is linked to their task specific motivational goals and dispositions. Behavioral tasks are designed to strain a targeted resource to differentiate individuals through measures of their performance. In this paper, we explore how student behavior on differentially gamed learning material relates to estimates of student motivational goals and dispositions. We leverage observations of students in two different courses using an intelligent tutoring system over an entire academic year. We use a previously validated heuristic model of gaming detection to label instances of gaming. Each student's tendency to game is estimated separately using highly gamed and non-highly gamed sections of the course. Each estimate of student gaming is compared to pre-course self-reported measures of student motivations. Results indicate that in naturalistic settings, gaming on more challenging materials is less influenced by student motivations and potentially a result of adaptive learning behaviors. Similarly, student gaming estimates using only non-highly gamed material are significantly related to all targeted motivation measures. Implications and future directions are discussed.

Motivation, Self-regulation, Gaming, Measurement, Intelligent Tutoring System

1. INTRODUCTION

Students in the US currently spend on average between 20-25 hours per academic year on standardized testing [29]. The largest cost of formal standardized tests is the cost of lost learning opportunities for students. Additionally, these formalized, high-stakes assessments also lead to a range of other systemic effects, such as reductions in topical coverage and cultures of teaching to the test, that result in negative impacts to student learning [1]. While the need for measurement of student performance at all levels is necessary for the continued improvement of educational institutions, there is a need to identify solutions that balance the need for information on institutional performance with the learning needs of the student.

Steven Dang and Kenneth Koedinger "Exploring the Link Between Motivations and Gaming" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 276 - 281

The increased prevalence of digital learning resources in schools has created an opportunity to explore an alternative solution to standardized testing. [26] demonstrated the viability of leveraging longitudinal observations of student performance in an intelligent tutoring system to match assessments of student mathematics aptitude from standardized exams. Similarly, [31], demonstrated how the educational design process can be extended to designing of educational games to produce game-based activities that produce valid assessments of student skill.

Student cognitive skill is only half of the formula for student success; they must also have the motivation to apply those skills diligently over time to achieve [11]. Currently there are inadequate instruments available for high stakes measurement of student motivational constructs [13].

Self-regulation related learner behaviors are linked to student motivations. The characteristics of the context when students demonstrate failures to self-regulate their learning behaviors can be informative of their motivational goals [28], their perceived value of the activity [15], and their beliefs about their self-efficacy [32]. Drawing on design principles of psychometric behavioral tasks, we believe we can identify contexts that sufficiently load on student self-regulation to measure student motivations. In this paper, we seek to explore the feasibility of leveraging observations of students' self-regulation as measured by gaming the system behaviors to measure student motivational goals and dispositions.

2. MOTIVATION

We define motivation as the orienting and invigorating impact on both behavior and cognition of prospective reward [9]. For this study, we focus on a set of well-defined goals and dispositions that have been shown to influence student motivation and achievement.

A student's interest in a domain will influence the subjective value any task from that domain. This perceived expected value from completing a task influences students' self-regulation decisions [15]. Students vary in their beliefs about their ability to successfully complete a task, their self-efficacy, and this difference in appraisal affects motivation to apply effort to a task [4]. Effort regulation describes the ability of students to motivate themselves and persevere on a task in the face of difficulty or failure [24]. Growth mindset captures the beliefs students have about the nature of intelligence and whether or not it is malleable [14]. As with self-efficacy, mindsets impact motivation through task appraisals. Student goals in academic tasks can be described using a two dimensional representation of mastery vs performance and approach versus avoidance [33]. Students with mastery approach goals set goals to learn any assigned knowledge and skills. Students with performance approach goals are motivated by a desire to perform better than their peers, while performance avoidant students are motivated by goals to avoid performing worse than their peers.

3. RELATED WORK

A significant body of prior work has focused on assessing moment-by-moment motivation through detectors of affect [10] and engagement [12,18]. However, work analyzing the link between fine-grained behavioral measures and motivational goals and dispositions is much more limited.

[27] created a rational model of student affect that leveraged a range of individual attributes including Big 5 personality measures and achievement goals. This work established the value of students' achievement goals on predicting moment by moment motivations as inferred by affect.

Several researchers attempted to identify task specific behaviors that rationally should be linked to achievement goals. [20] attempted to relate help-seeking behaviors while using an ITS to achievement goals. Researchers expected mastery-oriented students to be more likely to use a glossary/index resource, while performance-oriented students might tend to ask for hints from the tutor instead. No significant relationship between self-reported achievement goals and help-seeking behaviors was found. However, task achievement goals as predicted by choice of help resources did relate to learning outcomes as would be predicted by achievement goal theory.

[25] expanded on this work and attempted to relate task choice, where descriptions of each task were closely linked to corresponding achievement goals, to self-reported achievement goals and learning outcomes. In this work, task achievement goals as inferred by task choice predicted learning outcomes for the lesson but did not align with self-reported achievement goals. However, self-reported achievement goals were more predictive of course outcomes. Researchers speculated that self-reported goals might reflect an average tendency to be motivated by particular goals over a range of tasks within the domain and thus explaining alignment with more aggregated measures such as course outcomes.

Gaming the system, a pattern of behavior where students abuse the design of the learning environment to answer a particular question, is a well-documented behavior that has been linked to poor learning outcomes [2]. In [3], the authors test the relationship between a range of student motivations and gaming the system behaviors across two different ITS's. The study results supported a link between gaming behaviors and some motivational measures but not others. One of the strongest results indicated that student's attitudes and interest towards the domain was related to observed gaming frequency. There was also strong support for a link between experiences of frustration and gaming as well as a lack of drive to motivate themselves on tasks in general as well as in the face of challenge. The results demonstrated mixed or weak support for a relationship with growth mindset and perceptions of the helpfulness of the ITS help resources. Interestingly, the researchers failed to identify a relationship between observed gaming and performance goals, though the performance goal measures were not drawn from validated achievement goal instruments. Furthermore, this study used strictly observed gaming frequencies. Subsequent work has identified the joint role of contextual and student factors in explaining gaming behaviors [19,21].

In this paper, we seek to answer two main research questions. Research Question #1: How does the relationship between gaming and measures of motivation differ when gaming estimates are derived from either raw observations of gaming or using random effects models that account for both student-level and contextual variation. Research Question #2: How does student performance

on educational content with varying degrees of gaming frequency relate to their different motivational goals and dispositions?

4. THE DATASET

For this study, we used a dataset drawn from [16] that was collected as part of a year-long study [6] in a suburban middle school in a mid-atlantic state.

The students used the Carnegie Learning Cognitive Tutor software (CogTutor). The CogTutor software provides adaptive instruction based on a fine-grained skill representation of the domain. The application divides problems into steps that must be answered individually and each map to independent skills in the domain model. Student practice problems are selected according to whether they have demonstrated mastery of necessary skills. The instruction is also scaffolded, allowing students to request multiple levels of hints at every step of the problem, providing on-demand problem scaffolding that provides increasingly informative support to the students. The data logs generated by the software are transformed into the standard learning data format specified by [16] before being utilized in this analysis. This format specifies how long students spend on every interaction, whether the action was correct, incorrect, or a hint, and what skill is associated with a specific problem step. Each interaction is represented as a single student transaction in the dataset, which includes over 2M such transactions across all students analyzed.

The dataset includes 189 students across 7 pre-algebra classes and 5 geometry classes. The population is predominantly white/Caucasian with only 2% of the sample being non-white. 56% of the students are female and 22% received either free or reduced lunch. The classes used the tutor for an entire academic year with an average of close to two class periods per week on the tutor. While the original dataset included 240 students across both of these courses, students with incomplete grade and survey responses were eliminated.

Additionally, some students and curricular sections were excluded due to having low observations in the data. The median student was observed during at least 40 sessions. However, 18 students were eliminated because EDA indicated these students as different from most others. The excluded students were observed in less than 20 class sessions and completed on average 780 total interactions with the system over the course of the year. By contrast, the median student completed about 15k transactions over the course of 40 sessions on average. These students were excluded from analysis because they appear unengaged and/or unmotivated, but there are so few observations of their behavior that drawing any conclusions from limited data is more prone to unobserved confounds.

Similarly, transactions from 31 sections are excluded from the dataset because they were observed with less than 6 students completing any work in the section. These sections are excluded because such sections might be measurements of only the fastest working or highest achieving students, thus introducing a bias to observations of gaming within those sections.

4.1 Motivational Measures

In addition to fine-grained student log data, several survey measures were collected at the beginning of the course to measure students' pre-course motivational goals and dispositions. Each scale utilized was drawn from well-validated instruments. Survey measures include scales for interest in math [17], self-efficacy [5], effort regulation [24], growth mindset [8] and achievement goals [33]. Questions from each scale are included in Figure 1 below. Each question was answered using a 5-point Likert rating, and responses

for each scale were summed to represent students' motivation along each dimension.

Interest in Math	
1.	Math is practical for me to know
2.	Math helps me in my daily life outside of school
3.	It is important to me to be a person who thinks mathematically
4.	Thinking mathematically is an important part of who I am
5.	I enjoy the subject of math
6.	I like math
7.	I enjoy doing math
8.	Math is exciting for me
Self-Efficacy	
1.	I am confident that I will do well in math class
2.	I expect to do well in math
3.	I am confident that I can learn future math concepts
4.	Considering the difficulty of this course, I think I will do well in mathematics in the future
5.	I am confident that I will do an excellent job on future math problems.
Effort Regulation	
1.	I often feel so lazy or bored when I do homework for math class that I quit before I finish what I planned to do.
2.	I work hard to do well in math class even if I don't like what we are doing.
3.	When class work is difficult, I give up or only study the easy parts.
4.	Even when math class assignments are dull and uninteresting, I manage to keep working until I finish.
Growth Mindset	
1.	You have a certain amount of intelligence and you really can't do too much to change it.
2.	Your intelligence is something about you that you can't change very much.
3.	You can learn new things, but you can't really change your intelligence.
4.	No matter who you are, you can change your intelligence a lot.
5.	You can always greatly change how intelligent you are.
6.	No matter how much intelligence you have, you can always change it quite a bit.
Achievement Goals	
1.	My aim is to completely master the material presented in this unit.
2.	In this unit, I am striving to do well compared to other students.
3.	In this unit, my goal is to learn as much as possible.
4.	In this unit, my aim is to perform well relative to other students.
5.	In this unit, my goal is to avoid performing poorly compared to others.
6.	I am striving to understand the content of this unit as thoroughly as possible
7.	My goal is to perform better than the other students in this unit
8.	In this unit, I am striving to avoid performing worse than others.
9.	In this unit, my aim is to avoid doing worse than other students.

Figure 1. Motivational survey inventory

4.2 Gaming the System Behaviors

We used the heuristic model of gaming behaviors introduced by [22] as this model appeared to produce better kappa on unseen data from across multiple systems including the CogTutor. Using this model, individual transactions were labeled according to a taxonomy that captures a range of relevant behaviors such as thinking before a hint request, spending time reading hint requests, and variations of guessing behaviors. Transactions are labeled as gaming if they are a member of a set of subsequent transactions that matches one of the thirteen identified patterns by [22] and shown in Figure 2. The patterns encode two primary types of gaming: guessing and hint abuse. Guessing patterns include placing the same answer incorrectly into multiple available answer slots and answering the same question rapidly with very small

changes in the answer across attempts. Hint abuse patterns include not stopping to think about multiple subsequent errors before requesting help and rapidly requesting hints to seek a bottom-out hint, which in the CogTutor environment is simply the answer to the problem step given as the second or third hint.

Transactions are rolled-up into student steps, where each student step encapsulates metadata about all the transactions associated with a problem step until a correct answer is reached. Each student step is labeled as gamed if any transaction associated with the step was also labelled gamed. The resulting student step data was utilized to calculate student and content gaming frequencies.

The overall dataset included 3.5% gamed student steps. These numbers align reasonably well with gaming frequencies observed in prior work on CogTutor data. [2] found students gaming the system about 3% of the time based on in-classroom human observations. [23] found a slightly higher overall gaming frequency of 6.8% in their dataset utilizing the same detection model as used here. However, this deviation isn't so different that it is due to significant unobserved differences in the populations.

incorrect → [guess] & [same answer/diff. context] & incorrect
incorrect → [similar answer] [same context] & incorrect → [similar answer] & [same context] & attempt
incorrect → [similar answer] & incorrect → [same answer/diff. context] & attempt
[guess] & incorrect → [guess] & [diff. answer AND/OR diff. context] & incorrect → [guess] & [diff. answer AND/OR diff. context & attempt

Figure 2. Patterns of Gaming

The CogTutor content is organized hierarchically into multiple units. Each unit consists of several sections that themselves have multiple skills to be learned. Each section has problems that are divided into highly granular steps which each are associated with at least one skill. We chose to group observations at the section level to capture differences across the curriculum with sufficient resolution while having sufficient observations across students to make reasonable estimates of gaming frequency. The data included 206 sections with a mean gaming frequency of 1.95% and a standard deviation of 1.7%. A number of sections were found to have 0 observed gaming, while there was one extreme outlier section with a frequency of 12.12%.

Unlike in prior work, [2], no students were found to have never gamed throughout the year. The average student was observed gaming 3.66% of the time with a standard deviation of 1.16%. The minimum observed gaming frequency for students was 1.98% while the maximum observed was 11.95%.

4.3 Comparing measures of gaming

In this study, we generate four estimates of student gaming and compare these estimates of student gaming frequency to each motivational measure using partial correlations. In the partial

correlations, we control for gender, ethnicity, and free/reduced lunch status.

- (1) $\theta_{ObservedGaming} = \frac{xNumGamed}{N_{TotalSteps}}$
- (2) $P(Gamed) \sim (1 | Student) + (1 | Section)$
- (3) $\theta_{Gaming} = e^{\theta_{student}}$

To investigate RQ1, we calculate student gaming using frequencies calculated using only raw observations for each student as shown in Eq 1. We also predict gaming on each step using a random effects model with a random effect for student and section as shown in Eq 2. The model is fit over all observed student steps and the student gaming is found by calculating the exponential of the fitted random intercept, $\theta_{student}$, for each student as shown in Eq 3. To investigate RQ2, we divide the data into two subsets, hard sections and non-hard sections. We set an 80% quantile cutoff of 3.06% gaming frequency for each section to identify non-highly gamed sections. There were 164 non-highly gamed sections and 41 highly gamed sections. Again, the random effects model in Eq 2 was used for each data subset to estimate student gaming.

For RQ1, we expect student gaming estimates from the random effects model to better correlate with motivation because the model takes into account variance in gaming due to sections, which may not be observed for all students, as well as accounting for statistical noise due to sampling of a rare event.

For RQ2, we investigate the hypothesis informed by design principles of psychometric behavioral tasks. Measuring a targeted construct requires straining the resource and identifying a metric upon which to differentiate subject performance. Therefore, we expect estimates of student gaming using only highly gamed sections will have a more significant relationship with motivational variables compared to data without highly gamed sections.

5. RESULTS

The results of the partial correlation analysis are shown in Tables 1.1 and 1.2. The first row of both tables present evidence contrary to the results from [3]. Prior research found correlations with math interest, effort regulation, and growth mindset using only averages of observed gaming. However, in this dataset, only interest in the subject is related to gaming behaviors, and no other motivational measure has a significant correlation with student's gaming frequency.

On the other hand, the second row reflects correlations with student gaming estimated using a random effects model fitted with all of the data. In general, more motivational measures are correlated with these gaming estimates than those derived from the raw observations, which supports the hypothesis for RQ1. Comparing these results to [3], there are no direct measures of frustration, however it is possible that self-efficacy mediates whether student's experience of frustration explaining the correlation. Growth mindset is found to be marginally significant, which further bolsters the previous mixed evidence for a link between mindsets and average student gaming.

There are two cells where these correlations do not seem to agree with prior research. Effort regulation is expected to be correlated both as a matter of face validity as well as because prior research found a relationship between gaming and students' drive to persevere on academic work.

The link between achievement goals and gaming are mixed. In [3], the authors assessed performance goals using questions such as, "If

you had your choice, what kind of extra-credit projects would you most likely do". It is unclear how this question maps to achievement goals, however, performance approach goals are not significant as might be extrapolated from prior work. On the contrary, mastery approach and performance avoidance goals are correlated with gaming. This relationship is rationally derived from the theory on self-regulation and motivation, but not predicted by specific prior work. Overall, the random effects model yielded a significant relationship to more motivational constructs than gaming estimates from raw observations.

Table 1.1 Correlations with Motivation Measures

Data Subset	Math Interest	Self Efficacy	Effort Reg.	Growth Mindset
Observed	-0.22**	-0.10	-0.11	0.00
All	-0.17*	-0.16*	-0.11	-0.14(.)
High Gaming	-0.19*	-0.14(.)	-0.10	-0.11
Low Gaming	-0.16*	-0.19*	-0.16*	-0.14*

(.) -0.10 > p ≥ 0.05, * - p < 0.05, ** - p < 0.01, *** - p < 0.001

Table 1.2 Correlations with Achievement Goals

Data Subset	Mastery Approach	Performance Approach	Performance Avoidance
Observed	-0.03	-0.01	-0.05
All	-0.20**	-0.10	-0.15*
High Gaming	-0.14(.)	-0.08	-0.11
Low Gaming	-0.25***	-0.14(.)	-0.21**

(.) -0.10 > p ≥ 0.05, * - p < 0.05, ** - p < 0.01, *** - p < 0.001

The results from estimating gaming using only highly gamed sections, row #3, are contrary to what is expected. Many of the correlations that appear when using all of the data, are weakened or not significant when using only the hardest questions. While the loss of significance with some constructs could be an artifact of random sampling from the full dataset, this does not explain the results seen in the bottom row. When estimating gaming using only non-highly gamed sections, correlations arise with every available motivational construct as seen in the fourth row. This is an unlikely consequence of sampling from the population and supports the idea that student gaming performance on highly gamed questions is introducing additional noise to the available signal in the rest of the data. Thus, the evidence points towards student gaming behaviors in the non-highly gamed sections as being more informative of student motivations than behaviors in the highly-gamed sections where self-regulation is under greater strain.

5.1 Exploring High-gamed sections

One possible explanation for this counterintuitive result is that gaming in highly gamed sections could be due to poorly designed content instead of cognitively challenge questions. To quantify average section difficulty, we calculate the ratio of the number of steps where student's first transaction is either a hint request or an error to the total number of student steps observed for each section (the assistance score). The highly gamed sections do in fact appear to be more difficult sections. The average highly-gamed section has 18.3% assistance steps with a standard deviation of 5.2%. The easiest section in this subset was observed with 9.9% assistance. By contrast, the average non-highly-gamed section consisted of 9.6% assistance steps with a standard deviation of 4.1%. Therefore,

students required less overall assistance on the majority of non-highly-gamed sections than the easiest of the highly-gamed sections.

If the content, was in fact challenging to students, perhaps the average questions were beyond the abilities of students to answer. If students are unmotivated to try on difficult problems, then students should be most likely to game on the first encounter with a particular skill. As experience with a skill goes up, perceived difficulty should go down, thus monotonically reducing the probability of gaming with each practice opportunity. However, if a skill is beyond a student's ability and the student is sufficiently motivated to attempt to learn, then the student should be less likely to game on the first encounter of a skill than on subsequent encounters. In this case, after first encountering a skill, students are able to assess that the skill is too far beyond their abilities. On subsequent encounters with the skill, it is an adaptive behavior to abuse help resources or apply other gaming strategies to acquire the answer. Prior work has similarly found that not all gaming is harmful to learning [2], for instance students may be using hints as a form of worked example [30].

Figure 3. Gaming on 1st opportunity vs subsequent

In Figure 3, the observed gaming on 1st opportunities and all subsequent opportunities are compared for each section. Students in most highly gamed sections, in blue, are more likely to game of subsequent opportunities than the first. 70.7% of highly gamed sections share this characteristic as compared to 46.9% of non-highly gamed sections. This evidence, in addition to the lack of correlation between gaming on high-gamed sections and student's effort regulation supports the rational that gaming is sometime a somewhat desirable adaptive behavior for students and observations of gaming and in these sections should be treated differently than in other sections. In fact, the ratio of gaming on first opportunity to gaming on subsequent opportunities might be a valuable measure to incorporate into future motivational measurement models.

6. DISCUSSION

In this study, we demonstrate that leveraging random effects models to cope with statistical noise in observations of student's tendency to game on any given section better estimates student's gaming as related to their motivational goals and dispositions. Additionally, we provide initial evidence towards a measurement model of student's motivational goals and dispositions by leveraging observations of gaming. Results indicate a relationship

between gaming and motivation that involves an interaction with the difficulty level and prior experience with a problem.

Several correlations with gaming estimates appear contrary to prior research and merit further analysis. The significant correlation with both mastery approach and performance avoidance disagrees with the results found by [3]. This disagreement could be due to the independence of achievement goals from each other, where gaming may be driven by an aggregate motivation of all achievement goals. More analysis is necessary to bridge this seeming contradiction and understand how patterns of gaming across problems of varying difficulty and prior experience might support an interpretation of gaming as indicative of different achievement goal profiles.

Gaming frequency was leveraged as a proxy measure for a range of unencoded difficulty factors. While this includes factors such as poor classroom instruction or a poorly designed cognitive model, it also encapsulates difficulty of individual problem-steps. A natural next step would be to investigate how more detailed student skill models might improve estimates of perceived difficulty and corresponding enrich model understanding of the nuances of why students are gaming and how this relates to different motivational goals.

Prior work has also shown that on longer time-scales, motivational goals are not necessarily stable [7]. In this study, we looked for relationships between pre-course motivations and in-course gaming behaviors. For students with fluctuations in achievement goals or self-efficacy, the contexts in which such students tend to game or disengage from the lesson in other manners might similarly change. Further analysis is necessary to investigate whether variations in gaming over time are similarly reflective of variations in motivational goals and dispositions over time.

Furthermore, the study included a fairly large body of students, but the observations were still limited to a single school in a particular region of the country with limited ethnic and socio-economic status diversity represented in the sample. Such factors are known to be correlated with variations in the types and frequencies of gaming behaviors observed in the population [21]. As such, we exercise caution in extrapolating these relationships beyond this demographic group without further validation.

Nonetheless, the results presented in this work lay the groundwork for further investigation into measurement models of motivational goals and dispositions that leverage an understanding of the contexts that strain students' self-regulation. Such unobtrusive measurement models hold the keys to a future where schools can better utilize instructional time that is currently occupied by standardized test and test-specific preparation while still receiving the student, and class-level performance measures necessary to support continuous improvement.

ABSTRACT

Knowledge tracing allows Intelligent Tutoring Systems to infer which topics or skills a student has mastered, thus adjusting curriculum accordingly. Deep Knowledge Tracing (DKT) uses recurrent neural networks (RNNs) for knowledge tracing and has achieved significant improvements compared with models like Bayesian Knowledge Tracing (BKT) and Performance Factor Analysis (PFA). However, DKT is not as interpretable as other models because the decision-making process learned by recurrent neural networks is not wholly understood by the research community. In this paper, we critically examine the DKT model, visualizing and analyzing the behaviors of DKT in high dimensional space. We modify and explore the DKT model and discover that Deep Knowledge Tracing has some critical pitfalls: 1). instead of tracking each skill through time, DKT is more likely to learn an ‘ability’ model; 2) the recurrent nature of DKT reinforces irrelevant information that it uses during the tracking task; 3) an untrained recurrent network can achieve similar results to a trained DKT model, supporting a conclusion that recurrence relations are not properly learned and, instead, improvements are simply a benefit of projection into a high dimensional, sparse vector space. Based on these observations, we propose improvements and future directions for conducting knowledge tracing research using deep models.

Keywords

knowledge tracing, recurrent neural network, visualization

1. INTRODUCTION

Knowledge tracing has been investigated for decades. It allows Intelligent Tutoring Systems to infer which topics or skills a student has mastered, thus adjusting curriculum accordingly. Two widely used models are Bayesian Knowledge Tracing (BKT) [2] and Performance Factor Analysis (PFA)[11]. These models are designed in a way that each parameter has a semantic meaning. For example, the guess

and slip parameter in the BKT model reflect the probability that a student could guess the correct answer and make a mistake despite mastery of a skill, respectively. BKT attempts to explicitly model these parameters and use them to infer a binary set of skills as mastered or not mastered. In parallel with research in knowledge tracing models, deep neural networks have gained popularity in fields like Natural Language Processing and Computer Vision [3, 9]. Piech *et. al* proposed Deep Knowledge Tracing (DKT) [12], using recurrent neural networks for knowledge tracing. The DKT model achieves significantly improved results compared to BKT and PFA. However, its mechanisms are not well understood by the research community. That is, none of the parameters are mapped to a semantically meaningful measure which diminishes our ability to understand how DKT performs predictions. There have been some attempts to explain why DKT works well [8, 15], but these studies treat DKT model more like a black box, without studying the state space that underpins the recurrent neural network. In this work, we analyze and visualize the learned state space of the DKT model to better understand its mechanisms.

Recurrent neural networks can learn long range dependencies across many time steps. Long short term memory (LSTM) networks, gated-recurrent unit (GRU) networks, and numerous other variants enhance the vanilla RNNs in one way or another have achieved empirical success [6, 1, 5]. However, there are incredibly few works explaining what is happening under the hood. Karpathy *et al.* [7] provide a detailed analysis of the behaviors of recurrent neural network in language processing and find that some neurons are responsible for long range dependencies like quotes and brackets. We take a similar approach for analyzing the DKT model.

We aim to provide a better understanding of the DKT model and a more solid footing for using deep models for knowledge tracing. In this paper, we “open the box” of the DKT recurrent architecture, visualizing and analyzing the behaviors of the DKT model in a high dimensional space. We track activation changes through time and analyze the impact of each skill in relation to other skills. We modify and explore the DKT model, finding that some irrelevant information is reinforced in the recurrent architecture. Finally, we find that an untrained DKT model (with gradient descent applied only to layers outside the recurrent architecture) can be trained to achieve similar performance as a fully trained DKT architecture. Based on our analyses, we propose improvements and future directions for conducting knowledge

tracing with deep recurrent neural network models.

2. RELATED WORK

Bayesian Knowledge Tracing (BKT) [2] was proposed by Corbett *et al.* In their original work, each skill has its own model and parameters are updated by observing the responses (correct or incorrect) of applying a skill. Performance Factor analysis (PFA) [11] is an alternative method to BKT and it is believed to perform better when each response requires multiple skills. Both BKT and PFA are designed in a way that each parameter has its own semantic meaning. For example, the slip parameter of BKT represents the possibility of getting a question wrong even though the student has mastered the skill. These models are easy to interpret, but suffer from scalability issues and often fail to capture the dependencies between each skill because many elements are treated as independent to facilitate optimization.

Piech *et al.* recently proposed the Deep Knowledge Tracing model (DKT) [12], which exploits recurrent neural networks for knowledge tracing and achieves significantly improved results. Piesch *et al.* transformed the problem of knowledge tracing by assuming each question can be associated with a “skill ID”, with a total of N skills in the question bank. The input to the recurrent neural network is a binary vector encoding of skill ID for a presented question and the correctness of the student’s response. The output of the recurrent network is a length N vector of probabilities for answering each skill-type question correctly. The DKT model could achieve >80% AUC on the ASSISTmentsData dataset [4], compared with the BKT model that achieves 67% AUC. This is an exciting result because it demonstrates the possibility of using neural networks for knowledge tracing.

Despite the effectiveness of DKT model, its mechanism is not well understood by the research community. Khajah *et al.* investigate this problem by extending BKT [8]. They extend BKT by adding forgetting, student ability, and skill discovery components, comparing these extended models with DKT. Some of these extended models could achieve close results compared with DKT. Xiong *et al.* discover that there are duplicates in the original ASSISTmentsData dataset [15]. They re-evaluate the performance of DKT on different subsets of the original dataset. Both Khajah and Xiong’s work are black box oriented—that is, it is unclear how predictions are performed within the DKT model. In our work, we try to bridge this gap and explain some behaviors of the DKT model.

Trying to understand how DKT works is difficult because the mechanisms of RNNs are not totally understood even in the machine learning community. Even though the recurrent architecture is well understood, it is difficult to understand how the model adapts weights for a given prediction task. One common method used is to visualize the neuron activations. Karpathy *et al.* [7] provide a detailed analysis of the behaviors of recurrent neural network using character level models and find some cells are responsible for long range dependencies like quotes and brackets. They break down the errors and partially explain the improvements of using LSTM. We use and extend their methods, providing a detail analysis of the behaviors of LSTM in the knowledge tracing setting.

3. EXPERIMENT

To investigate the DKT model, we perform a number of analyses based upon the activations within the recurrent neural network. We also explore different training protocols and clustering of the activations to help elucidate what is learned by the DKT model.

3.1 Experiment setup

In our analyses, we use the “ASSISTmentsData 2009-2010 (b) dataset” which is created by Xiong *et al.* after removing duplicates [15]. Like Xiong *et al.*, we also use LSTM units for analysis in this paper. Because we will be visualizing specific activations of the LSTM, it is useful to review the mathematical elements that comprise each unit. An LSTM unit consists of the following parts, where a sequence of inputs $\{x_1, x_2, \dots, x_T\} \in \mathcal{X}$ are ideally mapped to a labeled output sequence $\{y_1, y_2, \dots, y_T\} \in \mathcal{Y}$. The prediction goal is to learn weights and biases (W and b) such that the model output sequence $\{h_1, h_2, \dots, h_T\} \in \mathcal{H}$ is as close as possible to \mathcal{Y} :

$$f_t = \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) \quad (1)$$

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \quad (2)$$

$$\tilde{C}_t = \tanh(W_C \cdot [h_{t-1}, x_t] + b_C) \quad (3)$$

$$C_t = f_t * C_{t-1} + i_t * \tilde{C}_t \quad (4)$$

$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) \quad (5)$$

$$h_t = o_t * \tanh(C_t) \quad (6)$$

Here, σ refers to a logistic (sigmoid) function, \cdot refers to dot products, $*$ refers to element-wise vector multiplication, and $[,]$ refers to vector concatenation. For visualization purposes, we log the above 6 intermediate outputs for each input during testing and concatenate these outputs into a single “activation” vector, $a_t = [f_t, i_t, \tilde{C}_t, C_t, o_t, h_t]$. In the DKT model, the output of RNN, h_t is connected to an output layer y_t , which is a vector with the same number of elements as skills. We can interpret each element in y_t as an

Figure 1: First two components of T-SNE of the activation vector for first time step inputs. Numbers are skill identifiers, blue for correct input, orange for incorrect input

Figure 2: The prediction changes for one student, 23 steps, correct input is marked blue, incorrect input is marked orange

estimate that the student would answer a question from each skill correctly, with larger positive number denoting that the student is more likely to answer correctly and more negative numbers denoting that the student is unlikely to respond correctly. Thus, a student who had mastered all skills would ideally obtain an y_t of all ones. A student who had mastered none of the skills would ideally obtain an y_t of all negative ones.

Deep neural networks usually work in high dimensional space and are difficult to visualize. Even so, dimensionality reduction techniques can help to identify clusters. For example, Figure 1 plots the first two reduced components (using t-SNE [10]) of the activation vector, a_t , at the first time step ($t = 0$) for a number of different students in the ASSISTmentsData. The numbers in the plot are skill identifiers. We use color blue to denote a correct response and the color orange to denote an incorrect response. From reducing the dimensionality of the a_t vector for each student, we can see that the activations show a distinct clustering between whether the questions were answered correctly or incorrectly. We might expect to observe sub-clusters of the skill identifiers within each of the two clusters but we do not. This observation supports the hypothesis that correct and incorrect responses are more important for the DKT model than skill identifiers. However, perhaps this lack of sub-clusters is inevitable because we are only visualizing the activations after one time step—this motivates the analysis in the next section.

3.2 Skill relations

In this section, we try to understand how the prediction vector of one student changes as a student answers more questions from the question bank. Figure 2 plots the prediction difference (current prediction vector - previous prediction vector) for each question response from one particular student (steps are displayed vertically and can be read sequentially from bottom to top). The horizontal axis denotes the skill identifier and the color of the boxes in the heatmap denote the change in the output vector y_t . The initial row in the heatmap (bottom) is the starting values for y_t for the first input. As we can see, if the student answers correctly, most of the y_t values increase (warm color). When an incorrect response occurs, most of the predictions decreases (cold color). This makes intuitive sense. We expect a number of skills to be related so correct responses should add value and incorrect responses should subtract value. We can further observe that changes in the y_t vector diminish if the student correctly or incorrectly answers a question from the same skill several times repeatedly. For example, observe from step 14 to step 19, where the student correctly answers questions from skill #113—eventually the changes in y_t come to a steady state. However, occasionally, we can also notice, a correct response will result in decreases in the prediction vector (observe step 9). This behavior is difficult to justify from our experience, as correctly answering a question should not decrease the mastery level of other skills. Yeung *et al.* have similar findings when investigating single skills [16]. Observe also that step 9 coincides with a transition in skills being answered (from skill #120 to #113). Even so, it is curious that switching from one skill to another

Figure 3: Activation vector changes for 100 continuous correctness of randomly picked 3 skills

Figure 4: Activation vector difference of randomly picked 3 skills through time

other would decrease values in y_t even when the response is correct. From this observation, one potential way to improve the DKT model could be adding punishment for such unexpected behaviors (for example, in the loss function of the recurrent network).

3.3 Simulated data

From the above analysis, we see from step 14 to step 19, the student correctly answers question from skill #113 and the changes in y_t diminish—perhaps an indication that the vector is converging. Also, from Figure 2, we see that for each correct input, most of the elements of y_t increase by some margin, regardless of the input skill. To have a better understanding of this convergence behavior, we simulate how the DKT model would respond to an *Oracle Student*, which will always answer each skill correctly. We simulate how the model responds to the *Oracle Student* correctly answering 100 questions from one skill. We repeat this for three randomly selected skills.

We plot the convergence of each skill using the activation vector a_t reduced to a two-dimensional plot using t-SNE (Figure 3). The randomly chosen skills were #7, #8, and #24. As we can see, each of the three skills starts from a different location in the 2-D space. However, they each converges to near the same location in space. In other words, it seems DKT is learning one “oracle state” and this state can be reached by practicing any skill repeatedly, regardless of the skill chosen. We verified this observation with a number of other skills (not shown) and find this behavior is consistent. Therefore, we hypothesize that DKT is learning a ‘student ability’ model, rather than a ‘per skill’ model like BKT. To make this observation more concrete, in Figure 4 we plot the euclidean distance between the current time step activation vector, a_t , and the previous activations, a_{t-1} , we can see the difference becomes increasingly small after 20 steps. Moreover, the euclidean distance between each activation vector learned from each skill becomes extremely small, supporting the observation that not only is the y_t output vector converging, but all the activations inside the LSTM network are converging. We find this behavior curious because it means that the DKT model is not remembering what skill was used to converge the network to an ‘oracle state.’ Remembering the starting skill would be crucial for predicting future performance of the student, yet the DKT model would treat every skill identically. We also analyzed a process where a student always answers responses incorrectly and found there is a similar phenomenon with convergence in an anti-oracle state.

Figure 5 shows the skills prediction vector after answering correctly 20 times in a row. We can see the predictions of most skills are above 0.5, regardless of the specific practice skill used by the *Oracle Student*. Now, we can safely say that the DKT model is not really tracking the mastery level of *each skill*, it is more likely learning an ‘ability model’ from the responses. Once a student is in this oracle state, DKT will assume that he/she will answer most of the questions correctly from any skill. We hypothesize that this behavior could be mitigated by using an “attention” vector during the decoding of the LSTM network [13]. Self attention in recurrent networks decodes the state vectors by taking a weighted sum of the state vectors over a range in the sequence (weights are dynamic based on the state vectors). For DKT, this attention vector could also be dynamically allocated based upon the skills answered in the sequence, which might help facilitate remembering long-term skill dependencies.

3.4 Temporal impact

RNNs are typically well suited for tracking relations of inputs in a sequence, especially when the inputs occur near one another in the sequence. However, long range dependencies are more difficult for the network to track [13]. In other words, the predictions of RNN models will be more impacted by recent inputs. For knowledge tracing, this is not a desired characteristic. Consider two scenarios as shown below: For each scenario, the first line is the skill numbers and the second line are responses (1 for correctness and 0 for incorrectness). Both two scenarios have the same number of attempts for each skill (4 attempts for skill #9, 3 attempts for skill #6 and 2 attempts for skill #24). Also, the ordering of correctness within each skill is the same (e.g., 1, 0, 0, 0

Figure 5: Prediction vector after 20 steps for skill #7, #8, #24

Figure 6: DKT predictions from two different students. The blue line is the prediction of correctness from DKT. The red line is the actual response correctness(1 or 0).

for skill #9).

Scenario #1									
Skill ID	6	6	9	9	9	9	24	24	6
Correct	1	1	1	0	0	0	0	0	1

Scenario #2									
Skill ID	9	9	9	9	6	6	6	24	24
Correct	1	0	0	0	1	1	1	0	0

For models like BKT, there is a separate model for each skill. Thus, the relative order of different skills presented has no influence, as long as the ordering within each skill remains the same. In other words, for each skill the ordering of correct and incorrect attempts remains the same, but different skills can be shuffled into the sequence. For BKT, it will learn the same model from these two scenarios, but it may not be the case for DKT. The DKT model is more likely to predict incorrect response after seeing three incorrect inputs

in a row because it is more sensitive to recent inputs in the sequence. This means, for the first scenario, first attempt of skill #24 (in bold) will be more likely predicted incorrect because it follows three incorrect responses. For the second scenario, first attempt of skill #24 (in bold) is more likely to be predicted correct. Thus the DKT model might perform differently on the given scenarios.

Figure 6 gives two typical excerpts from the real dataset for two students. In the top example, after several correct inputs, the DKT model has a high probability of predicting the next item correct, regardless of the skill (70%). Similarly, in the bottom example, after several incorrect inputs, the DKT model has a low probability of predicting the next item correct (8%), regardless of the skill. That means, if a student has mastered an easy skill previously but then fails three attempts of more difficult exercises, the DKT would predict that the student would also fail the already mastered skill. We are only giving two samples here due to limited space, but this kind of behavior is universal across students, which we will talk more next. Again, we hypothesize that this behavior could be mitigated by using an “attention” vector that allows the DKT to use the whole weighted history as additional inputs.

Table 1: Area under the ROC curve

	PFA	BKT	DKT	DKT (spread)	DKT (untrained)
09-10 (a)	0.70	0.60	0.81	0.72	0.79
09-10 (b)	0.73	0.63	0.82	0.72	0.79
09-10 (c)	0.73	0.63	0.75	0.71	0.73
14-15	0.69	0.64	0.70	0.67	0.68
KDD	0.71	0.62	0.79	0.76	0.76

Table 2: Square of linear correlation (r^2) results

	PFA	BKT	DKT	DKT (spread)	DKT (untrained)
09-10 (a)	0.11	0.04	0.29	0.15	0.25
09-10 (b)	0.14	0.07	0.31	0.14	0.26
09-10 (c)	0.14	0.07	0.18	0.14	0.15
14-15	0.09	0.06	0.10	0.08	0.09
KDD	0.10	0.05	0.21	0.17	0.17

Khajah *et al.* also alluded to this recency effect in [8]. In this paper, we examine this phenomenon in a more quantitative way. We shuffle the dataset in a way that keeps the ordering within each skill the same, but spreads out the responses in the sequence. This change should not change the prediction ability of models like BKT. The results are shown in Table 1 and Table 2 using standard evaluation criteria for this dataset. All results are based on a five-fold cross validation of the dataset. When comparing DKT on the original dataset to the “spread out” dataset ordering, we see that the relative ordering of skills has significant negative impact on the performance of the model. From these observations, we see the behaviors of DKT is more like PFA which counts prior frequencies of correct and incorrect attempts other than BKT and the design of the exercises could have a huge impact on the model (For example, the arrangements of easy and hard exercises).

3.5 Is the RNN representation meaningful?

Recurrent models have been successfully used in practical tasks like natural language processing [3]. These models can take days or even weeks to train. In a recently published paper, Wieting *et al.* [14] argue that RNNs might not be learning a meaningful state vector from the data. They show that a randomly initialized RNN model (with only W_o and b_o trained) can achieve similar results to models where all parameters are trained. This result is worrying because it may indicate that the RNN performance is due mostly to simply mapping input data to random high dimensional space. Once projected into the random vector space linear classification can perform well because points are more likely to be separated in a sparse vector space. The actual vector space may not be meaningful. We perform a similar experiment in training the DKT model. We randomly initialize the DKT model and only train the last linear layer (W_o and b_o) that maps the output of LSTM h_t to the skill vector, y_t . As shown in Table 1 and Table 2, the untrained recurrent network performs similarly to the trained network.

4. CONCLUSION AND FUTURE WORK

In this paper, we dive deep into the Deep Knowledge Tracing model. We have visualized and analyzed the behaviors of DKT through time using dimensionality reduction of the activations vector, a_t . We have also analyzed the temporal sequence behavior of DKT using qualitative and quantitative analyses. We find that the DKT model is most likely learning an ‘ability’ model, rather than tracking each individual skill. Moreover DKT is significantly impacted by the relative ordering of skills presented. We also discover that a randomly initialized DKT with only the final linear layer trained achieves similar results to the fully trained DKT model. In other words, the DKT model performance gains may stem from mapping input sequences into a random high dimensional vector space where linear classification is easier because the space is sparse. This is a worrying conclusion because it means the underlying recurrent representation may not be reliable nor semantically meaningful. Several mitigating measures are suggested in this paper, including the use of a loss function that mitigates unwanted behaviors and the use of an attention model to better capture long term skill dependencies. We leave evaluation of these suggestions to future work in the educational data mining community.

ABSTRACT

One of the essential problems, in educational data mining, is to predict students' performance on future learning materials, such as problems, assignments, and quizzes. Pioneer algorithms for predicting student performance mostly rely on two sources of information: students' past performance, and learning materials' domain knowledge model. The domain knowledge model, traditionally curated by domain experts, maps learning materials to concepts, topics, or knowledge components that are presented in them. However, creating a domain model by manually labeling the learning material can be a difficult and time-consuming task. In this paper, we propose a tensor factorization model for student performance prediction that does not rely on a predefined domain model. Our proposed algorithm models student knowledge as a soft membership of latent concepts. It also represents the knowledge acquisition process with an added rank-based constraint in the tensor factorization objective function. Our experiments show that the proposed model outperforms state-of-the-art algorithms in predicting student performance in two real-world datasets, and is robust to hyper-parameters.

student modeling, predicting student performance, tensor factorization

1. INTRODUCTION

The popularity of online learning services and massive open online courses has led to extensive growth in the amount of student activity and learning data. As the number of students and learning materials increase in these online systems, the need for automatic sense-making from this data, educational data mining, becomes more evident. One of the important tasks in educational data mining is accurately predicting students' performance (PSP). PSP can be used in early detection of high-risk students that may fail or quit a class, in class evaluation and course planning activities,

and in learning material recommendation to students.

Many successful PSP techniques aim to predict students' performance in a problem by modeling their state of knowledge in different concepts required by that problem. To do this, pioneer and recent PSP techniques rely on the availability of a domain knowledge model that maps problems to concepts [19, 5, 25]. However, given the vast scope of learning materials in today's online learning systems, such domain knowledge models may not be available. Ideally, a PSP model should be able to work without requiring such a predefined map.

Additionally, a successful data mining model for PSP should be capable of considering specific characteristics of student learning process: (a) that students gain their knowledge on concepts over time, by practicing different problems, (b) that they may forget some of the gained knowledge, (c) that this knowledge gain is a gradual process, and (d) that learning can happen differently for different students in different problems and different times. Finally, to provide better insight to students and teachers, such a model should also be interpretable considering these characteristics. Previous research in the literature only cover some of the limitations above.

In this paper, we propose a student performance prediction model, Ranked-Based Tensor Factorization (RBTF), considering all the above requirements. To model student sequences on problems, we represent their scores over time as a three-dimensional tensor. To avoid the need for a predefined domain knowledge model, we propose a tensor factorization model for PSP, that maps problems and student knowledge in a lower-dimensional "latent" concept space. Representing student knowledge in this lower-dimensional space leads to a soft-membership approach that provides more flexibility by avoiding strict assignment of student knowledge to discrete "knowledge states". By learning student, problem, and time-based biases in this model we take into account the differences between students, problems, and times in the learning process. To capture the gradual learning requirement, we impose a rank-based constraint on student knowledge variables, that allows for occasional forgetting of concepts, but imposes a generally positive learning trend.

In our experiments, we study the proposed model in comparison with two state-of-the-art baseline PSP algorithms, on two real-world datasets. Our experiments show that our

model performs better than both baselines in the task of predicting student performance. We experiment with the performance and sensitivity of our model with various hyper-parameters.

Paper Outline. The remaining of the paper is organized as follows. Section 2 provides a brief literature review of the related work. Section 3 describes our model (RBTF) and the parameter learning steps. Section 4 evaluates extensively RBTF and other baselines on two real datasets. Lastly, Section 5 concludes the paper and suggests some directions for future works.

2. RELATED WORK

Many pioneer solutions to the problem of predicting student performance are based on either regression models [19] or Bayesian knowledge tracing (BKT) [5]. Regression-based models, such as performance factor analysis (PFA), try to predict students' performance using a pre-defined domain model that maps learning material to knowledge components [19]. PFA, which is based on learning factor analysis [4], takes into account prior successes and failures of a student on knowledge components associated with the current problem.

BKT is a constrained two-state hidden Markov model that models student knowledge in each knowledge component (KC) as two binary states: "known" and "unknown". It learns the probability of transitioning between these two states, and probabilities of students' success and failure in each KC, given their state of knowledge. Despite being successful in PSP for certain datasets, this model, in its original form, does not consider continuous states of knowledge or soft membership to knowledge states. Moreover, BKT does not capture the relationships between KCs, and is not personalized for individual student. Additionally, BKT also relies on a pre-defined domain model. Recently, new BKT-based models aim to address some of these problems [2, 9, 29]. For example, Pardos and Heffernan has addressed BKT's non-personalized modeling in [18, 17]. Song et al. proposed PSFK in [25] to address PSP when students encounter a knowledge component for the first time. But, these models rely on labeled problem knowledge components or concepts. Later, Gonzalez-Brenes and Mostow proposed a topical hidden Markov model that jointly learns the domain model and predicts student performance [10, 8]. However, this model has two restricting assumptions: that at each attempt, the student works on one skill of a problem, and that the students do not forget any acquired skills.

Recently, other approaches inspired by recommender systems' research and factorization models have been used for PSP. Despite being successful, these approaches are not tailored for the educational data mining problems specifically since they do not explicitly model student learning as a learning gain process. The matrix-factorization approaches in this area do not consider student sequences and only rely on a snapshot of student performance. For example, Thai-Nghe and Schmidt-Thieme proposed a multi-relational factorization student model that considers multiple relations between students and tasks, but does not consider student sequences [27]. Later, Nedungadi and Smruthy proposed a similar multi-relational matrix factorization approach ex-

ploring the effect of modeling biases [16]. Sahebi et al. also proposed another multi-relational learning approach that learned student performance according to canonical correlation analysis [22]. Non-negative matrix factorization has been used to improve performance predictions [28]. Pero et al. compared collaborative filtering techniques for the task of PSP in a small dataset [20]. Elbadrawy et al. predict student performance using their interactions with the learning management system to achieve a higher accuracy [7].

Some other recommender system-based approaches consider student sequence, but do not explicitly model knowledge gain in students. For example, Thai-Nghe et al. explored different factorization models, including tensor factorization, to predict student performance [26]. Sahebi et al. [23] studied educational data mining methods, such as PFA and BKT, with matrix and tensor factorization approaches, from the recommender systems literature, for PSP. Almutairi et al. have used tensor and coupled-matrix factorization to predict course-based student performance [1]. However, their tensor decomposition models do not explicitly model students' knowledge gain.

Although there have been some promising research on PSP that consider student sequence without requiring a domain model, these approaches have been limited. For example, SPARse Factor Analysis (SPARFA) by Lan et al. that uses Kalman filters to jointly learn the domain model, student knowledge, and the underlying question difficulties, can be very expensive to learn due to having a big state space [12]. Sahebi et al. have proposed a feedback-driven tensor factorization algorithm that can model student gradual knowledge acquisition [24]. But, their model has a strict constraint that does not allow for forgetting the concepts by students. Lindsey et al. proposed a non-parametric Bayesian technique that can refine the expert-labeled skills. However, they simplify the problem by finding coarse-grained skills as they restrict each problem to have exactly one skill [14]. In this paper, we propose a tensor factorization model for predicting student performance that does not require domain knowledge, models problems and student knowledge as soft-membership of latent concepts, and can model student sequences and gradual knowledge increase.

3. RANK-BASED TENSOR FACTORIZATION (RBTF)

Here we present our model, rank-based tensor factorization, by which we aim to predict students' performance in problems, considering their performance sequence and knowledge growth. Our proposed model is inspired by the recommender systems domain. Our choice of a recommender systems-based model was because of two main reasons: a) student performance similarities, and b) problem similarities. First, we consider that students with similar knowledge levels will perform similarly in solving problems. Second, we assume that a student will have similar performance on two problems with similar concepts. Recommender-based factorization models consider these two expectations. However, as discussed in the introduction section, a successful student model needs to include additional considerations. One of which is that knowledge gain is a gradual process for students, which happens over time. As students interact with learning materials, such as problems, they learn from them.

To represent this time-based process, we model students' activity sequences as a series of attempts on problems. For the student performance data to be represented according to these assumptions, we represent student sequences in a three-dimensional tensor (\mathcal{Y}), that has the student, problem, and time (attempt) dimensions. Each cell $y_{a,s,p}$ in this tensor represents student s 's score in problem p , that she has chosen to study at attempt a .

The core idea of the aforementioned assumptions is the notion of "concepts": gradual learning can be viewed as gaining knowledge in course concepts; student knowledge-based similarities are based on how much they mastered each of the concepts; and problem similarities are defined on how their represented concepts are shared. However, in many online educational systems, concepts are undefined and difficult to measure. In these systems, there are no "observed" features defined as problem concepts or knowledge components. Hence, we propose to discover shared "latent" features between students and problems as representatives for the notion of concepts. We model each problem as a vector of k latent concepts, that shows the importance of each latent concept in that problem. Also, we model each student's knowledge at any time point as another vector of the same latent concepts.

We assume that a student s 's performance on problem p at time a is a result of her existent knowledge in the latent concepts required by the problem. Accordingly, we model estimated student score $\hat{y}_{a,s,p}$ as a dot product between problem's latent concept vector \mathbf{q}_p and student's knowledge in those concepts $\mathbf{t}_{a,s}$:

$$\hat{y}_{a,s,p} \approx \mathbf{t}_{a,s} \cdot \mathbf{q}_p \quad (1)$$

To maintain the interpretability of our model, we enforce latent variables in \mathbf{q}_p to be non-negative. Here, by choosing the number of concepts (k) less than the number of problems and students, we are representing students and problems in a lower-dimensional latent space that can better capture student and problem similarities (our second and third assumptions). However, the model in Equation 1 does not consider differences in factors such as student ability, problem difficulty, or student cohort strength. For example, students' average score in a more difficult problem is expected to be less than their average score in an easier problem. To address this issue, we add student, problem, and attempt biases (b_s , b_p , and b_a), in addition to an overall cohort bias (μ) to our model:

$$\hat{y}_{a,s,p} \approx \mathbf{t}_{a,s} \cdot \mathbf{q}_p + b_s + b_p + b_a + \mu \quad (2)$$

To learn the parameters of this problem (\mathcal{T} , Q , b_s , b_p , b_a , and μ) we minimize the objective function in Equation 3. The first component calculates the squared difference between observed student scores and estimated student scores. The last three components are for regularizing biases, student knowledge, and problem concepts for generalizability purposes.

$$\begin{aligned} \mathcal{L}_1 = \sum_{a,s,p} (\hat{y}_{a,s,p} - y_{a,s,p})^2 \\ + \lambda(b_s^2 + b_p^2 + b_a^2) + \lambda_1 \|\mathbf{t}_{a,s}\|^2 + \lambda_2 \|\mathbf{q}_p\|^2 \end{aligned} \quad (3)$$

The model in Equation 2 does not address our gradual learning assumptions for students. To capture this gradual learning, we can assume that a student's knowledge ($\mathbf{t}_{a,s}$) increases over time. But, we should also note that this knowledge increase depends on the problems that the student selects to solve and the concepts presented in them. As a result, we can translate this knowledge increase as an increase in estimated student scores in problems ($\mathbf{t}_{a,s} \cdot \mathbf{q}_p$). In other words, we expect that student s 's predicted scores at attempt a to be larger than her scores at attempt $a-1$:

$$\mathbf{t}_{a,s} \cdot \mathbf{q}_p - \mathbf{t}_{a-1,s} \cdot \mathbf{q}_p \geq 0$$

In reality, this knowledge increase can be non-monotonic. For example, a student may forget some concepts after a while. For this reason, we propose to use a rank-based model for student knowledge gain, that allows knowledge loss to happen for students, but penalizes it. Using this rank-based model, we aim to maximize the difference between the aggregation of all students' scores on all questions at each attempt versus the attempts before that. Hence, we would like to maximize \mathcal{L}_2 in Equation 4. Here, $\sigma(\cdot)$ is the sigmoid function, defined as $\sigma(x) = 1/(1 + e^{-x})$. Sigmoid function is selected because of its superiority in rank-based recommendation systems [21, 6]. The term $\log(\sigma(\mathbf{t}_{a,s} \cdot \mathbf{q}_p - \mathbf{t}_{j,s} \cdot \mathbf{q}_p))$ means that for attempt a of student s , the *ranking* of s 's score at a is higher than the one of s at j with $j < a$.

$$\mathcal{L}_2 = \sum_{j=1}^a \sum_s \sum_p \log(\sigma(\mathbf{t}_{a,s} \cdot \mathbf{q}_p - \mathbf{t}_{j,s} \cdot \mathbf{q}_p)) \quad (4)$$

To capture the dynamics between all assumptions, we combine the minimization of \mathcal{L}_1 in Equation 3 and maximization of \mathcal{L}_2 in Equation 4. Our final objective is to minimize the loss function in Equation 5. The hyper-parameter ω is to control the relative strictness of knowledge increase versus the importance of having a more accurate estimate of student performance.

$$\begin{aligned} \mathcal{L} = \sum_{a,s,p} (\hat{y}_{a,s,p} - y_{a,s,p})^2 + \lambda_1 \|\mathbf{t}_{a,s}\|^2 + \lambda_2 \|\mathbf{q}_p\|^2 \\ + \lambda(b_s^2 + b_p^2 + b_a^2) - \omega \sum_{j=1}^a \sum_s \sum_p \log(\sigma(\mathbf{t}_{a,s} \cdot \mathbf{q}_p - \mathbf{t}_{j,s} \cdot \mathbf{q}_p)) \end{aligned} \quad (5)$$

Learning the Parameters: By using stochastic gradient descent algorithm to minimize \mathcal{L} , we find student knowledge of each latent concept at any point, the importance of each latent concept in each problem, and estimation of student score in each problem at any attempt. Recall that the parameters we want to infer are \mathcal{T} , Q , b_s , b_p , b_a ,

and μ . For the cohort bias μ , we assign the average score of all students on all problems [11], i.e. $\mu = \frac{\sum_{a,s,p} y_{a,s,p}}{\sum_{a,s,p} \mathcal{I}(a,s,p)}$ where $\mathcal{I}(a,s,p)$ is an indicator function returning 1 if the tuple (a,s,p) is in our training set; otherwise 0.

4. EXPERIMENTS

In the following, we evaluate our model in comparison with two state-of-the-art methods in the task of predicting student performance. Further, we analyze how our solution models students' learning process by looking at students' knowledge gain in course concepts. Eventually, we experiment on RBTF's sensitivity to various hyper-parameter settings.

4.1 Dataset and Experiment Setup

For experiments, we use the Canvas network dataset¹ which is available online [3]. Canvas Network hosts many freely available open online courses. In addition to learning modules, each course can have different types of assignments, discussions, and quizzes. In this platform, participants are not limited to a specific sequence of learning material or assignments. The dataset is anonymized such that student IDs, course names, discussion contents, submission contents, or course contents are not available.

Dataset	#students	#problems	#attempts	Avg. attempts
Course 1	531	91	87	29.92
Course 2	2597	32	30	12.73

Table 1: Dataset Statistic.

We select two courses in Canvas and denote them as Course 1 and Course 2. The selected courses have the most number of quizzes in the whole dataset. We consider each quiz as a problem in our model. Quizzes are graded between zero and a maximum possible score. For consistency, we normalize the quiz grades between zero and one. Table 1 shows the statistics of these two courses. As shown in the table, Course 2 has more students but less number of problems and attempts than Course 1.

The data of each course is represented as a list of tuples (*attempt, student id, quiz id, grade*). We randomly split 80% of tuples for training and the remaining (i.e. 20%) for testing.

Hyper-parameter Setting: In the performance prediction experiments (Section 4.2), we set $\omega = 0.5$, $\lambda_1 = \lambda_2 = 0.1$ and regularization of bias $\lambda = 0.001$. The number of concepts is set to 3.

4.2 Student Performance Prediction

In this section, we compare the prediction performance of RBTF with other baselines to evaluate the prediction ability of RBTF.

Baselines: To compare the prediction performance, we employ the following two baselines:

¹<http://canvas.net>

- **Feedback-Driven Tensor Factorization (FDTF)** [24]: It is a tensor factorization model specifically tailored to predict students' performance. It considers students' gradual learning process. However, the assumption of hard constraint on knowledge increase in students limits its modeling capacity. Also, it does not include biases and does not allow for the concepts to be forgotten by students.
- **SPARse Factor Analysis (SPARFA)** [13]: SPARFA is a probabilistic factor analysis approach that calculates the probability of a student's correct response to a problem. It does not require a predefined domain knowledge model. However, it does not consider students' sequences. To adapt it to our problem, we use the probability scores instead of the predicted student grade.

Metrics: We use two measures to evaluate the performance prediction task. Since our main goal is to predict student scores or grades, we would like to measure how close our predictions are to the actual student scores. To do this, we use the root mean squared error (RMSE). The lower the value of RMSE, the better the model.

Since many performance prediction models focus on predicting students' success and failure as a binary value, instead of their score [13, 5], we also employ accuracy for performance comparison. To do this, we regard scores greater than 0.5 as success and the rest as failure. Unlike RMSE, the higher the value of accuracy, the better the model.

Dataset	RMSE			Accuracy		
	RBTF	FDTF	SPARFA	RBTF	FDTF	SPARFA
Course 1	0.12	0.27	0.59	92.5%	85.2%	81.7%
Course 2	0.2056	0.2116	0.567	95.24%	92.8%	87.41%

Table 2: Prediction Performance.

Results: Table 2 shows the prediction performance of our model (RBTF) and the two baselines (FDTF and SPARFA) on the two datasets. As we can see, both tensor factorization models (RBTF and FDTF) perform better than SPARFA in both courses. This shows the importance of considering student sequences in predicting their performance. Also, we can see that RBTF performs better than FDTF in both courses. This shows that, even though modeling sequential knowledge increase in students is important, this increase should not be strictly monotonic and should be flexible to allow for occasional forgetting of concepts.

4.3 Hyper-parameter Sensitivity Analysis

In this section, we study RBTF's sensitivity to hyper parameter values. First, we experience on the balance between training error on student performance fitting (\mathcal{L}_1 in Equation 3) versus modeling student knowledge increase (\mathcal{L}_2 in Equation 4) on the generalizability of our model. To do this, we measure the test error by varying hyper-parameter ω , that controls this balance in Equation 5. Then, we capture the effect of the number of concepts on RBTF's performance by varying k in Equation 5 and measuring its error on test data.

Dataset	0.01	0.25	ω 0.5	0.75	1.0
Course 1	0.191	0.128	0.12	0.137	0.141
Course 2	0.233	0.2064	0.2056	0.2154	0.2224

Table 3: RMSE with different value of ω and number of concept is 3.

Sensitivity to ω : Recall that ω controls the trade-off between having an accurate estimation of student performance and the constraint of knowledge increase. A larger value of ω , imposes more contribution of knowledge increase constraint to the performance of RBTF, and a smaller value of ω dictates a stricter fit of student performance to the training data. We use different values of ω from 0 to 1 and measure RBTF’s RMSE corresponding to these values. For other parameters, we use the default values mentioned in Section 4.1. Table 3 presents the performance of RBTF with different values of ω on the two datasets. From the table, we observe that $\omega = 0.5$ yields the best performance of RBTF and it is consistent for the two datasets. However, the results from Course 2 dataset is more sensitive to the changes in ω . One reason for this can be the smaller number of attempts and more sparsity of Course 2 dataset, compared to Course 1 dataset, that can lead to easier overfitting to training data.

Dataset	3	k 5	10	15
Course 1	0.12	0.122	0.127	0.128
Course 2	0.2056	0.206	0.2065	0.2065

Table 4: RMSE with different value of number of concepts and $\omega = 0.5$.

Sensitivity to k : Recall that, in our model, concepts are latent lower-dimensional representations of student performance and problems over attempts. They can be used to model the similarity between students and problems. To measure the effect of the number of concepts k , we tune the value of k while using the default values for other parameters (see Section 4.1). We measure the RMSE of RBTF by changing k . Table 4 shows the results. From the table, we observe that increasing the value of k makes RBTF perform slightly worse. This finding is consistent in both datasets. However, RBTF is relatively robust to k as this increase in error is minor.

5. CONCLUSION AND FUTURE WORK

In this paper, we proposed a novel rank-based tensor factorization method (RBTF), which is able to predict the performance score of students by considering the gradual learning of students as a ranking problem. Our model has the flexibility to present student knowledge as a soft-membership of latent concepts, only requires activity sequences of students, and discovers individualized student knowledge model including biases. Our extensive evaluations show that RBTF outperforms state-of-the-art baselines in both root mean square error and accuracy measures. Also, we show our models robustness to hyper-parameters by experimenting the balance between knowledge ranking and performance fitting parts of the model, and by varying the number of latent concepts.

There are several directions to extend this research work

further. In this work, we experiment on performance prediction within the same course. This model can be used to experiment on between-course performance predictions. Another application of our model is to detect knowledge gaps in students and recommend useful learning materials to them. Moreover, contingent on the availability of a domain knowledge model, this work can be extended to improve the existing domain knowledge model. Recent studies show that order and length of students’ activities are essential for understanding students’ performance [15]. So, integrating these features can enhance the prediction performance of our model.

ABSTRACT

Understanding large-scale patterns in student course enrollment is a problem of great interest to university administrators and educational researchers. Yet important decisions are often made without a good quantitative framework of the process underlying student choices. We propose a probabilistic approach to modelling course enrollment decisions, drawing inspiration from multilabel classification and mixture models. We use ten years of anonymized student transcripts from a large university to construct a Gaussian latent variable model that learns the joint distribution over course enrollments. The models allow for a diverse set of inference queries and robustness to data sparsity. We demonstrate the efficacy of this approach in comparison to others, including deep learning architectures, and demonstrate its ability to infer the underlying student interests that guide enrollment decisions.

1. INTRODUCTION

Education researchers increasingly recognize the need to understand the sequential accumulation of college coursework into academic pathways. In [2, 23], Bailey et al. call for change in how colleges organize course offerings to enable more efficient pathways. Rather than presenting a bewildering array of courses, cafeteria-style, they recommend “guided pathways” through academic offerings. Baker [3] builds on Bailey’s work, suggesting “meta-majors” for simplifying choice without curtailment of options. Meta-majors entail combining coursework supporting multiple majors into larger, substantively coherent content domains. Baker proposes social-network analytic techniques to discover opportunities for building meta-majors. All of these authors argue that rather than limiting choice, such interventions can yield more tractable programs, faster degree completion, and lower cost for both students and schools.

Such reforms can be enabled by analysis of data corpora

describing the academic sequences of prior student enrollments. For example, some courses may be de facto prerequisites for other courses, whether listed as “required” or not in formal catalogue entries. Similarly, “odd” delays in taking particular courses, or unexplained detours in course selection, can be symptoms of unintended scheduling conflicts.

In the service of such reforms, we offer a model of course enrollment capable of efficient inference over hundreds to thousands of classes. Our generative model captures the full joint distribution of course enrollments and can be used to sample potential pathways for any given student. The model’s complexity allows us to determine an underlying “typography” of students, from implicit course-taking patterns to differing levels of novelty in their academic pathways relative to the overall population of paths.

2. BACKGROUND & MODELS

Predicting course enrollment decisions may be viewed as a problem of multi-label classification: the task of assigning a subset of labels to each data point in a collection. In context of academic course enrollments, each data point is a student and the labels are courses enrolled. The problem of modeling all possible enrollment choices scales exponentially with the number classes ($O(2^N)$), which motivates a statistical approach. Probabilistic graphical models (PGMs) and deep neural networks are perhaps the most prominent methods for stochastic models of high-dimensional data. As our motivation in this work is not simply high accuracy but also interpretability and inference, we focus on PGMs, which fare better on those aspects and are amenable to scaling adequate for our empirical setting.

2.1 Latent Variable Models

Latent variable models are a subclass of PGMs in which some variables are never observed in training data and are thus “latent.” These models are more computationally demanding than fully observed models, but also are able to capture complex structure in data without supervision.

2.1.1 Models of Conditional Independence

Among the simplest and most commonly used latent variable models is the naive Bayes model with hidden variable H taking discrete values h_i and observations X . In the enrollment setting, $X = [x^0, \dots, x^N]$ and $x^i = [x_0^i, \dots, x_M^i]$ with

Nate Gruver, Ali Malik, Brahm Capoor, Chris Piech, Mitchell Stevens and Andreas Paepcke “Using Latent Variable Models to Observe Academic Pathways” In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 294 - 299

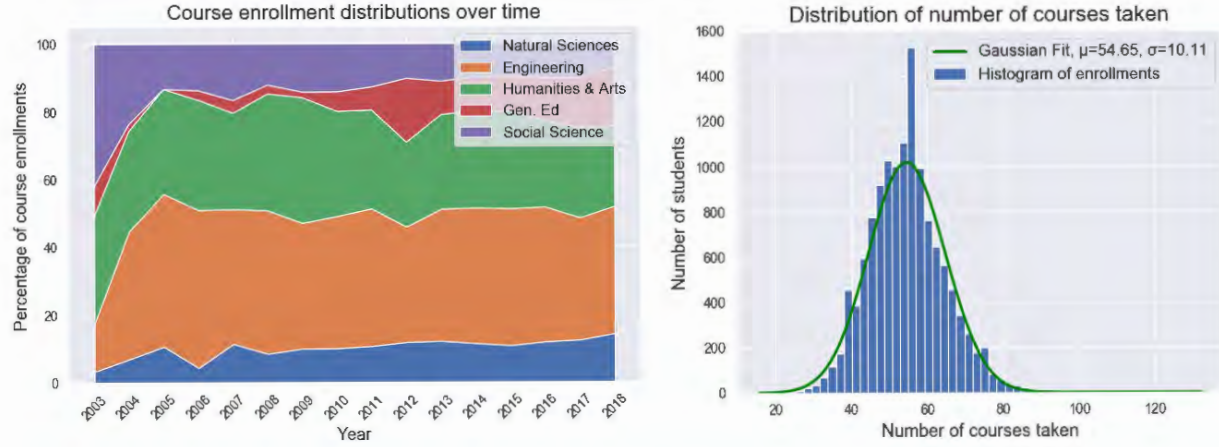

Figure 1: Top: A stacked area plot of enrolled courses per university sub-school per year. Bottom: A histogram of the number of courses taken by each individual student with a Gaussian fitting.

$x_j^i \in \{0, 1\}$ (0 denoting no enrollment and 1 an enrollment). The generative process of the model is described below:

$$\begin{aligned} h^i &\sim \text{Multinomial}(\theta) \\ x_j^i | h^i &\sim \text{Multinomial}(\phi_j) \end{aligned}$$

Given the value of the hidden variable, each individual probability of enrolling in a course is independent. This is a poor inductive bias because enrollment decisions often influence one another, and the number of courses taken by a student in a given year is dependent on the courses taken. It is easier to capture these two facets of the data if we can model enrollments jointly, without strong independence assumptions.

2.1.2 Gaussian Mixture Model

Any joint probability distribution over all discrete combinations of $x^i \in \{0, 1\}^m$ requires $2^m - 1$ parameters and is thus intractable. One possible solution is relaxation of the discrete problem to a real-valued vector space with $\bar{X}^i \in \mathbb{R}^m$ and

$$x_j^i = \begin{cases} 1 & \bar{x}_j^i > 0 \\ 0 & \text{else} \end{cases}$$

By training a model over \bar{X} , we can take advantage of real-valued distributions with much smaller parameter spaces.

The Gaussian Mixture Model (GMM) is an archetypal latent variable model for real-valued data [22]. We can describe a GMM by generative process below:

$$\begin{aligned} h^i &\sim \text{Multinomial}(\theta) \\ \bar{x}^i | h^i &\sim \mathcal{N}(\mu, \Sigma) \end{aligned}$$

We can modify the GMM for the setting of multi-label classification by providing an unbiased estimator of the probability of each binary sample:

$$\begin{aligned} P(x = [1, 0, \dots, 1]) &= P(\bar{x}_0 > 0, \bar{x}_1 < 0, \dots, \bar{x}_0 > 0) \\ &\approx \frac{1}{K} \sum_{i=1}^K \Phi(\vec{0}; \mu(y^i), \Sigma(y^i)) \mathbb{1}[y^i > \vec{0}] \end{aligned}$$

where y^i are samples drawn from a multivariate normal over a subset of the variables in x and $\mu(y^i)$, $\Sigma(y^i)$ are the parameters of a multivariate normal conditioned on the value of y^i . More detail on this estimator is provided in the online posting of this paper.

At face value, it might seem odd to model enrollments as Gaussian-distributed. We choose this particular model both because it makes our real-valued relaxation tractable and because we think it is reasonable to assume enrollments within each cluster will be fairly unimodal and smooth, especially as sample sizes increase.

2.1.3 Contextual Mixture Model

Hidden Markov Models (HMMs) are a common extension of stationary mixture models to sequential data [21]. In these models, the single latent variable is replaced with a Markov chain of hidden states. This model is naturally recursive, a property that is extremely useful when modeling processes that are positive recurrent. However, as enrollments often exhibit a strict order and returning to previous states is unlikely, we prefer a model that is strictly time-dependent or, as we will call it here, “contextual.” In general any Contextual Mixture Model (CMM) can be expressed using a Hidden Markov model, but enforcing this structure allows us to incorporate priors that significantly improve the chances of training a plausible model.

For a CMM with Gaussian emission probabilities, we have

$$\begin{aligned} h^0 &\sim \text{Multinomial}(\theta) \\ h^{t+1} | h^t &\sim \text{Multinomial}(\phi^t) \\ \bar{x}^t | h^t &\sim \mathcal{N}(\mu_i^t, \Sigma_i^t) \end{aligned}$$

Note that the parameters of the transition and emission distributions are different for each timestep. Figure 2 shows a diagram of our proposed model in plate notation.

The small, discrete latent space of our model offers highly interpretable representations compared with the continuous latent vector space of neural architectures (see Fig. 4) and inference is highly efficient as the model has low tree-width.

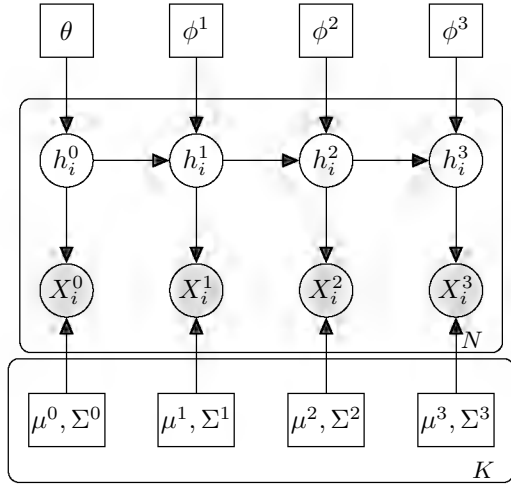

Figure 2: Graphical representation of contextual mixture model using plate notation

Our discrete probability estimator also allows modeling of all courses jointly, which is essential in this setting.

2.1.4 Parameter Learning

There are two primary methods of learning the parameters of the model we propose: expectation-maximization (EM) [8, 5] and gradient descent [6] on the log-likelihood objective. The approximate probability estimate of the model also creates the possibility for differing levels of precision in accordance with the amount of computation one is willing to invest. For a highly biased learning process, one can simply train the model on data shifted from $[0, 1]$ to $[-1, 1]$ using the exact probability estimate. For a less biased learning process, one can use the probability estimator described in Section 2.1.2 and unbiased estimator of the gradient with respect to the model parameters. For more details, see the online posting of the paper.

2.2 Baseline Models

In Section 4 we present a comparison of our model with three baseline models. The first of these is a naive Bayes model with the strongest model assumptions. The second is tree-augmented naive Bayes [9], which adds dependencies between variables to better model the joint density. Both models with trained with EM.

The last model we use for comparison is a Variational Autoencoder (VAE)—a deep generative model [15]. We use a simple VAE with two fully connected layers in the encoder and decoder, trained on binary cross-entropy loss.

It is important to note that while the VAE offers a good comparison point, the type of conditional inference (over sets of courses) that we describe for our Gaussian relaxation are not tractable in a standard VAE framework. In fact, VAE models can suffer from suboptimal inference in general when there is overfitting of the decoder network [7]. This issue is particularly concerning in this setting with relatively small sample size.

3. EXPERIMENTS

In this section, we describe the data used to train the model presented in Section 2 and how we evaluated them during training.

3.1 Data

We use eighteen years of course enrollment data from a large private university in the United States. The data comprise approximately 30,000 student enrollment records with fields for course name and student major. We removed part-time and summer students from the dataset, limiting the analyses presented here to full-time academic-year enrollments only.

Figure 1 shows two basic visualizations of the data after pre-processing. There are at least two notable takeaways from these plots. First, the proportion of enrollments in each academic division within the university remains relatively stable through most of the time period represented in the dataset. We use this fact to aggregate over time without explicitly modeling changes in enrollment patterns. Second, the fact that the number of courses taken is approximately Gaussian-distributed shows that enrollment patterns are not intensely multi-modal; thus the assumptions of probabilistic model are plausible.

In what follows we replace full course names with abbreviated proxies to enable universal legibility. For example, CS1 corresponds to the introductory computer science class and “Alg” or “AI” correspond to algorithms or artificial intelligence classes respectively.

4. EVALUATION

4.1 Mean-Field Evaluation

Though we can compare many of the models under consideration with log-likelihood alone, some only offer an approximate lower bound (VAEs). Thus we provide another evaluation metric that can be used to compare any model that can generate sampled enrollments.

For this loss function, we compare the empirical enrollment distributions in samples from our model and the distributions of the hold-outs. Let p_j^t be the probability that class j is taken by any given student in the hold-out data, and p_j^s be the corresponding probability in the samples. We take as our error, $E(p^t, p^s)$ with

$$E(p^t, p^s) = \sum_j (p_j^t - p_j^s)^2$$

which approximates the distance between the two true multivariate distributions—the distribution of our model and the distribution of the data—if all the variables were independent (mean field approximation).

4.2 Sample Quality

In Figure 3 we compare the performance of our model on *hold-out data* relative to baseline models described in Section 2.2. We also include a direct comparison of the best performance for each model in Table 1.

In Figure 3 we can see that our proposed model outperforms the two baselines across the board. It also is evident that the VAE baseline suffers bad generalization as the complexity of

Figure 3: Plots of the error for the proposed model and other models. The parameter K is the dimension of the latent space.

Model	Sample Error	Inference Acc.
Deep Generative	1.01	N / A
Naive Bayes	0.78	60%
Tree-Augment Naive Bayes	0.76	66%
Our Gaussian	0.72	86%

Table 1: A direct comparison of the best performance from each model on hold-out data

the model increases. These models were trained adaptively, according to performance on the validation set, and thus are not simply underfitting due to increased training complexity.

In comparing the graphical models, increased complexity—both in the observation model and latent space—leads to lower error. As the error calculation itself makes an independence assumption, it is not surprising that the performance of all three graphical models is relatively close. The true dominance of the model proposed here is perhaps most evident in the inference task of Table 1, described in Section 5.3.

4.3 Visualizing Hidden Variables

Beyond using the loss function defined in Section 4.1, we can also examine the hidden states of a trained model to validate the learning process. In particular, we can investigate whether the hidden space captures semantically meaningful categories. Figure 4 shows a visualization for our model trained on CS majors. The clusters in the grid correspond to required courses for three different concentration within the major¹, and the color shows the most likely latent state assigned by the model to each course. As we can see, courses within the same concentration are assigned strikingly similar latent states by the model, suggesting that the model captures a semantically meaningful notion of the different concentrations in its hidden state. Therefore, if there are unknown correlations in course enrollments—for example

¹These requirements were taken from the department website: <https://exploreddegrees.stanford.edu/schoolofengineering/computerscience>.

Figure 4: A visualization of the semantic meaning captured by the latent space of the model. Coloring corresponds to hidden state, and translucency indicates the confidence of the model.

many AI and biology courses taken together—this model could bring these patterns to the fore, allowing administrators an insight into possible ways to improve their degree concentrations.

5. APPLICATIONS

In this section we present results from two different experiments performed with our proposed model. These applications demonstrate only a fraction of the model’s scope, but show its power to provide insights.

5.1 Quantifying Enrollment Likelihood

One of the useful applications made simple by our generative model is in quantifying enrollment likelihood. A model trained on student enrollments will approximate the distribution of the training data. Thus if we evaluate the likelihood of a new student’s enrollments given the model, we can get a sense of how this student differs from the training examples. Taking this principle to its extreme, we can train a model for each student on every other student’s enrollments, allowing us to model exactly how much each particular student varies from the typical.

By examining the classes taken by students who are evaluated as high versus low likelihood, we see that the model captures at least two meaningful axes of variance. Firstly, it recognizes that it is rare for students to take a very diverse set of courses spanning many academic subjects. This insight is demonstrated in Figure 6, which shows the average coursework for each type of student. The second insight that the model captures is the spectrum of ambition. More specifically, the model places very low probability on the small subgroup of students that take up to 30 computer science classes and places high probability on taking just the core requirements of the degree². Atypical students take about 20 more courses than their counterparts on average.

²We can identify this trend by looking at the exact classes that are most commonly taken by these students e.g. the core requirements.

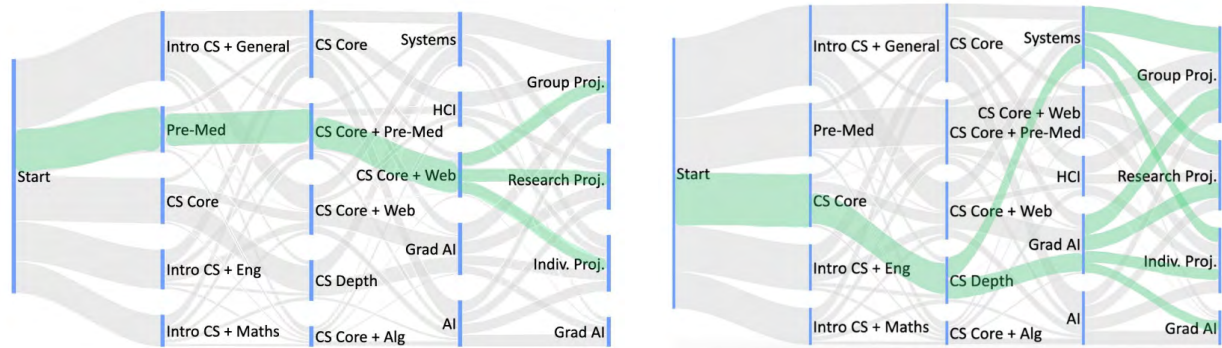

Figure 5: Two shadings of the same Sankey diagram constructed from the CMM trained on CS undergraduate enrollments. Top: A common path taken by students engaging in pre-med requirements is highlighted in blue. Bottom: A common path for students committed to in-depth study of computer science is highlighted.

Figure 6: Pie charts representing the difference between enrollment patterns captured by the model. Sections correspond to the average number of courses taken in a academic subject.

5.2 Understanding Pathways

Another capability of the model presented here is the ability to analyze sequences of enrollments, from inferring likely paths between X and Y, to uncovering unspoken student strategies. We can display this visually using Sankey diagrams in which the width of the line between adjacent segments is proportional to the transition probability between the corresponding hidden states in the model. Figure 5 shows this style of Sankey for CS students. In this diagram, we can note the two types of paths highlighted in the diagram. The first of these captures students who were actively taking the pre-medical requirements freshman and sophomore year. These same students were subsequently much more likely to take depth courses later and were more likely to focus on web development of information systems in their depth courses. We can contrast these students with the students that are highly committed to the CS major and its core classes starting freshman year. These students are much more likely to enroll in depth classes by their sophomore year and are predisposed towards the systems and AI concentrations within the major.

5.3 Inferring Intermediate Classes

Another unique capability of our model is inferring the likelihood of intermediate classes. Given the classes taken freshman year and goal classes for senior year, the model can place a likelihood on intermediate classes. One possible use case for this ability is inference of soft or tacit prerequisites for courses.

To test this aspect of the model, we predicted whether students would take each of 5 common classes in their sophomore year given freshman and senior year enrollments. We were able to recover the correct enrollment with around 86% probability. From this result it is clear that the model can learn a sensible joint distribution over multi-year enrollments. We can compare this performance with that of the baseline models in Table 1, noting a substantial gain.

An even more interesting use case of this inference ability, however, is not simply prediction of common courses, but the potential for improving course selection tools. Only a model that captures the temporal dependencies across all courses is capable of offering helpful insights for goal-directed course selection.

6. PRIOR WORK

Much of the prior work on enrollment modeling in the university setting is dedicated purely to predictive models of future course enrollment [13, 18, 24] and academic performance [16, 11]. These models are largely incapable of producing the kinds of insights shown here. Preliminary work has also seen application of clustering algorithms to enrollments in form of latent variable models like Latent Dirichlet Allocation (LDA) [17] and recurrent neural networks [20].

Much of the state-of-the-art research in student decision modeling is now found in the study of massive open online courses (MOOCs). Gardner and Brooks [10] provide a thorough overview of modern models for the problem setting. Of note, Balakrishnan and Coetzee use a Hidden Markov Model (HMM) to predict attrition in MOOCs [4]. Similarly, Al-Shabandar et al. use Gaussian Mixture Models (GMMs) to cluster MOOC students at each timestep, and thus identify clusters of students that are likely to withdraw from the courses [1]. Both of these models resemble ours though their task is prediction of simple binary outcomes.

Work in course recommender systems is also inspiring. Khorasani et al. create a recommender based on a Markov model [14]. Jiang et al. use a neural-network system [12], and add the choice of using grade considerations to create custom course recommendations (also see [19]). This second model yields extremely compelling results, but is not capable of the broad range of inference queries possible with our model.

7. CONCLUSION & FUTURE WORK

We have presented a new probabilistic model that is capable of capturing joint relationships between course enrollments, while also allowing for powerful inference queries. There is, however, at least one important drawback to our approach: the strictly Markovian character of the model. Although this assumption allows us to easily learn model parameters, in practice the enrollments observed at one timestep will impact those sampled at the next timestep. Because of this inductive bias our approach is effective with less training data than, for example, a recurrent neural net, and is therefore more easily deployed for institutions smaller in size than our case university.

We emphasize the potential for future work that links data of the sort investigated here with other rich information, such as demographic information describing students, and earned grades. Models incorporating such information could meaningfully identify differences between course trajectories of particular kinds of students, providing insights into how academic policies and programs might be tuned to benefit specific constituencies.

ABSTRACT

Peer-grading is commonly adopted by instructors as an effective assessment method for MOOCs (Massive Open Online Courses) and SPOCs (Small Private online course). For solving the problems brought by varied skill levels and attitudes of online students, statistical models have been proposed to improve the fairness and accuracy of peer-grading. However, these models fail to deliver accurate inference in the SPOCs scenario because affinity among students may seriously affect the objectivity and reliability of students in the peer-assessment process. To address this problem, this paper proposes a human-machine hybrid peer-grading framework, including an automatic grader to ensure reasonable peer grades before the Bayesian models are utilized to infer the true scores. This framework can significantly eliminate the severely biased grades by those undutiful students, and thus improve the accuracy of the true-score estimation in the Bayesian peer-grading models. Both simulated and real peer-grading datasets in our experiments demonstrate the effectiveness of this new framework for SPOCs.

Keywords

peer grading, human-machine hybrid algorithm, Bayesian model, auto-grader, SPOCs

1. INTRODUCTION

SPOCs is a version of MOOCs used locally with on-campus students. Despite the difference between SPOCs and MOOCs that SPOCs has the relatively smaller number of students than a MOOCs course [8], a SPOC course needs the same peer-grading process as a MOOC course when the instructor has to evaluate hundreds of open-ended essays and exercises

such as mathematical proofs and engineering design problems within a deadline.

Previous research efforts on peer-grading suggest that there is a great disparity between the observed scores presented by student graders and the true scores given by the instructor. This is because students sometimes can't perform grading tasks as a professional instructor with the right skill and dedication. In the process of peer grading of SPOCs, every student grader needs to submit his answer to the problems of home assignments, and evaluate other peer's submissions according to the rubrics provided by the course instructor. The previous models [7][6] mainly adopt a Bayesian-based approach by considering the major factors affecting the aggregation of peer graded scores including the bias and reliability of every student grader.

These peer grading algorithms mostly designed for MOOCs courses may have poor performance in the setting of SPOC courses because they ignore another important factor – student attitude toward their grading tasks. Due to affinity among students in a SPOC course, they tend to assign random scores to other submissions without seriously evaluating their peers' homework. Even worse, in our real experiment, we found that some students simply give a full score to every submission assigned to them. Therefore, such an undutiful grading behavior violates the basic assumption in those Bayesian statistical models and unavoidably generate data noises that severely degrade the performance of the models. Our simulation and real experiment confirm that the models produce inaccurate estimations for final scores in the process of per grading [3].

To address the problem, this paper proposes a novel human-machine hybrid framework that combines assessment effort of both human and machine for peer-grading. The framework adopts a document classifier as an auto-grader that evaluates students' submissions to estimates their scores, and compares the scores with the peer-graded scores. Then, it attempts to filter out the unreasonable peer-graded scores that are significantly different from its estimations, and retain these legitimate scores for the statistical models. In this way, it can alleviate the negative impact of student ran-

dom grading behavior and improve the overall performance of peer-grading models. Experimental results on the actual and simulation datasets demonstrate that our hybrid framework outperform the original peer-grading models in terms of the true-score estimation accuracy without placing too much extra workload on course teaching assistants (TAs).

The rest of paper is organized as follows: Section 2 discusses the related work of our research. Section 3 elaborates the main problems of current models in the peer grading of our SPOCs and explains the motivation of combining the machine and the human effort in peer grading. Section 4 describes the design of the human-machine hybrid framework for peer-grading in detail. Section 5 presents our experimental results.

2. RELATED WORK

The focus of this paper is to combine the power of human graders and a machine grader to improve the predictive ability of the existing peer grading models. Numerous papers have been published on the field of peer-grading research. Most researchers attempt to tackle with the peer-grading problems from the two aspects: statistical methods for accurately inferring true scores and incentive mechanism to motivate and regulate student grading behaviors.

One of the major research topics in peer-grading is to build a Bayesian statistical model that can accurately infer the true-scores of student submissions. Such models were proposed in [7] and [6] for peer-grading in MOOC courses with bias and reliability of student graders as the major latent factors. In [10], Ueno utilize Item Response Theory to model the score estimation, difficulty of problem and a grader's capability as parameters in the IRT equation. The major limitation of these models is caused by their assumption that every student follows a statistical model in the peer-grading process. But in practice, especially in the scenario of SPOCs, students' grading behavior actually are heavily affected by their motivation and attitude towards peer-grading tasks. Some students grade homework in a dutiful manner whilst others simply assign scores randomly. Thus, a single statistical model cannot describe all the possible grading strategies among these students in a SPOC course.

The problem of student grading behavior has received attention from academic researchers in the field of game theory. Recently, peer prediction mechanism has been proposed to incentivize truthful reports from individual students in the process of peer-grading [3][1]. Without the ground truth scores for every submission to verify against, designers of peer prediction mechanism often introduce comparison algorithms that compare grading results among multiple student graders and enforce penalties on those whose evaluation outcomes are different from their peers. But peer-prediction has its inherent limitation because there are potentially multiple Nash equilibria where students might be able to coordinate to avoid penalty without revealing their informative signal truthfully. Even when the peer-prediction mechanisms do offer a truthfully equilibrium, they also always induce other uninformative equilibria [2]. In the settings of SPOCs, affinity among students make it highly possible for them to collude in the peer-grading process to cheat the peer-prediction mechanisms.

Our human-machine hybrid framework is complementary to the research efforts on the statistical peer-grading models and spot-checking mechanisms of peer-prediction. The auto-grader in our framework can help to eliminate unreliable assignment grades so as to ensure only quality grades are passed onto the statistical models such as the PG family model. In this way, the auto-grader can be adopted in spot-checking mechanisms and work as an online supervisor to perform checking tasks on behalf of TAs and update TAs with its screening results.

The development of reliable auto-grader is widely regarded as a challenging task. Many researchers such as [9][5] designed neural network-based auto-graders to evaluate open essays. The state-of-art automatic graders can't complete grading tasks in a full autonomous way, especially for science essays and technical reports in domain-oriented courses. Thus, our framework only assumes an automatic grader with limited classification capability and regard it as an intelligent assistant that can work with course instructors and TAs in the process of peer-grading.

3. PROBLEM ANALYSIS OF PEER GRADING MODELS

In the section, we first introduce the peer grading (PG) models, then discuss the problems of the PG models when they are applied in the SPOC settings. Through the simulation experiment, we analyze fault tolerance of the PG models with the increase in the number of undutiful students.

3.1 Peer Grading Models

We apply the PG models [7][6][4] in the SPOCs scenario, which are Bayesian graph models with the latent factors including the biases and reliabilities of the peer graders. These models of Eq (1)(2)(3)(4) define z_u^v the observations grade which is affected by the latent factors including b_v , τ_v , and the learner's true grade s_u . The parameter ρ denotes factors that affect the reliability, and the remaining parameters β , η , μ , γ , λ in Eq (1)(2)(3)(4) are hyper-parameters.

$$\tau_v \sim \mathcal{N}(\rho, 1/\beta_0) \quad (1)$$

$$b_v \sim \mathcal{N}(0, 1/\eta_0) \quad (2)$$

$$s_u \sim \mathcal{N}(\mu_0, 1/\gamma_0) \quad (3)$$

$$z_u^v \sim \mathcal{N}(s_u + b_v, \lambda/\tau_v) \quad (4)$$

3.2 Limitations of the PG models in SPOCs

There are two major factors that may prohibit SPOCs students from performing peer-grading tasks in a fair and accurate way. First, students without the right knowledge and dedication may regard peer-grading tasks as unnecessary burdens and decide to give the assignments random scores. Second, affinity among SPOCs students who often interact with each other in the same campus or even classroom may drive them to assign higher grades to her or his peers' submissions. Both factors can result in high deviation between the observation grades z_u^v and the ground-truth grade. We run the simulation experiment to evaluate the impact of student's attitude of peer assessment and analyze the tolerance of the PG models against data error generated by student graders. Based on the configuration of the simulation, we extend the PG models as follows: Assume that each student becomes a dutiful or an undutiful students with a certain

Figure 1: The correlation between the RMSE of the PG model and the proportion of undutiful students in the simulation.

probability each time they review. Define the number of students with undutiful grading attitude as $p \in [1, n]$. Although the value of p can also be 0, here we define the value of p starting from 1 for the convenience of calculation, and the n is the total number of all students. Define a grading strategy set D where every element $d_i \in D$ denotes a particular distribution corresponding to the strategy to follow. The set D contains the distributions (5) and (6):

$$z_u^v \sim \mathcal{N}(s_u + b_v, \lambda/\tau_v) \quad (5)$$

$$z_u^v = x \pm \text{random}(y) \quad (6)$$

The Eq (5) represents the strategy distribution in which the observed scores are presented by the good students with dutiful grading attitude, and the Eq (6) represents the other strategy distribution in which the observed scores are presented by the undutiful students with high deviation. In Eq (6), x is the set to the average grading scores based on experiences and y is set to an random value with the range $[0, 20]$. For simplicity, we assume that a student determine his/her choice of the grading strategy before he accepts the grading task and will not change in the middle of the grading process.

Figure 1 shows that the RMSE of the prediction grades has a linear correlation with the proportion of undutiful peer graders and its value ranges in $[10, 25]$. This result remains even when we change the parameters (x, y) in the Eq (6). The expression of RMSE can be defined in Eq (7), where $X_{model,k}$ denotes the specific prediction grade prediction generated by the PG models for an exercise report k , and $X_{true,k}$ denotes the corresponding ground truth score of the exercise report k .

$$RMSE = \sqrt{\frac{\sum_{k=1}^n (X_{model,k} - X_{true,k})^2}{n}} \quad (7)$$

We can expand the Eq (7) by separating the errors generated by the dutiful group and undutiful group. First we define $e_k = X_{model,k} - X_{true,k}$ ($k \in [1, n]$), then we define $p\bar{e} = \sum_{i=1}^p e_i$ ($p \in [1, n]$) denotes the sum of the set $A = \{e_i | i \in [1, p]\}$ and $(n-p)\bar{f} = \sum_{j=p+1}^n e_j$ denotes the sum of the set $B = \{e_j | j \in [p+1, n]\}$. So, we transform the Eq (7) into Eq (8) on the condition that each element in A and B are

equal,

$$RMSE \cong \sqrt{\frac{p(\bar{e}^2 - \bar{f}^2)}{n}} + \bar{f}^2 \quad (8)$$

Because of the assumption $|\bar{e}| \geq |\bar{f}|$, the value of RMSE increases with p changing from 1 to n . Thus we can summarize that the grading attitude of the students can significantly affect the performance of the PG model.

3.3 Comparison among grading error distributions in the simulation and actual datasets

By comparing different inference performance of the PG models in both simulation experiments and the real dataset, we analyze the effect of the features of bias b_v and reliability τ_v on the precision of inferring true score s_u . In the Gibbs sampling process for fitting the PG models, the Eq (9) updates s_u in iterations. where the variable z_u^v is a constant value, besides the τ_v and b_v , the others are hyperparameters. From Eq (9) we can infer that the main factors affecting the true grade s_u include a grader's bias and reliability.

$$s_u \sim \mathcal{N}\left(\frac{\gamma_0 \mu_0 + \beta_0 \tau_{u_i} + \sum_{v:v \rightarrow u_i} \frac{\tau_v (z_u^v - b_v)}{\lambda}}{\gamma_0 + \beta_0 + \sum_{v:v \rightarrow u_i} \frac{\tau_v}{\lambda}}, \frac{1}{\gamma_0 + \beta_0 + \sum_{v:v \rightarrow u_i} \frac{\tau_v}{\lambda}}\right) \quad (9)$$

In order to verify the conclusion of our analysis, we compare the grading errors of the PG models in simulation experiments and the real dataset. The real dataset was collected in the SPOC course on Computer Network in our university. We build an online learning system to support the session of the course with the total enrollment of 724 students. Figure

Figure 2: The distributions of errors in three simulation datasets and the actual dataset. Fig A, B and C denote the histogram of grading errors generated by simulation experiments. Fig D denotes the distribution of the real dataset based on the Computer Network course.

2 shows that the simulation and actual datasets have a very different error distribution. Fig 2A assumes that every student's grading behavior follows the gaussian model defined

in Eq (5). In contrast, the real dataset in Fig 2D indicates that many students' grading behavior doesn't satisfy the gaussian distribution. In order to further confirm the conclusion, we have conducted the other simulation experiments, in which we configure 40% undutiful students and 60% undutiful students to follow the random grading behavior defined in Eq (6), respectively. The results as shown in Fig 2B and Fig 2C demonstrates a similar error range to Figure 2D. These observations suggest that students in the SPOC experiment tend to exhibit random grading behavior. Clearly, such a high deviation of the peer grades in the real dataset from their ground truth is the reason why the PG models cannot achieve the low RMSE as we expect.

4. THE HUMAN-MACHINE HYBRID PEER GRADING FRAMEWORK

This section presents the design of our human-machine hybrid framework in detail, as shown Figure 3. The main idea of the framework is to use the auto-grader as an anomaly detector to screen the peer grades generated by undutiful students. The framework consists of three major components including a homework Auto-Grader, a Score-Filter and the PG models.

Figure 3: The human and machine hybrid framework of peer grading.

In the process of peer grading, the system first allocates the tasks for each student to perform their peer-grading tasks. After the Auto-Grader receives a score for a submission, it estimates a score for the same submission, and passes the estimation to the ScoreFilter. The ScoreFilter is responsible for comparing the Auto-Grader's estimation with the original peer score, and abandoning the peer score if the deviation between these two scores goes beyond the predefined threshold. With the co-ordination of the Auto-Grader and the ScoreFilter, the framework divides the student submissions into two groups: one group includes the submissions with legitimate peer grades that can be aggregated by the PG model for the grade inference, the other includes those without valid peer grades that have been sent to TAs for evaluation.

4.1 Naive Bayesian based Classifier as Auto-Grader Implementation

Based on Naive Bayesian method, we design a weak text classifier as the Auto-Grader in the hybrid peer grading framework. Each course assignment report often contains several problems. Thus the Auto-Grader's design consists

of several classifiers, each of which classifies one problem in the assignment report. The grade classification results for all the problems of the assignment are mapped into scores based on its rubric and combined together as the total score of the assignment report.

4.2 Score Filtering and Postprocessing

The ScoreFilter in the hybrid human-machine grading framework adopts a simple filtering process. It computes the absolute value of the difference between grades estimated by the Auto-Grader and the peer-graded scores, sorts the scores in a descending order, and filter out the top 20% with the highest deviation values. The design of the score filter involves two major issues: The threshold for dropping unreasonable scores and the post-processing strategy for supplementing abandoned scores.

The Error Threshold of Score Filtering

Because our Auto-Grader is a weak classifier, we need to consider the classification error of each sub-problem of a homework report when we use the Auto-Grader to evaluate each sub-problem. We define the following equation to calculate the grading error.

$$Threshold_{error} = \sqrt{\frac{\sum_{i=1}^n (x_i - a_i)^2}{n}} \quad (10)$$

In the Eq (10), $x_i \in x_1, x_2, \dots, x_n$ denotes the score given by a student grader, $a_j \in a_1, a_2, \dots, a_n$ denotes the score estimated by the Auto-Grader. The value of n presents the number of the problems in an assignment. We use Eq (10) to predict the error for each peer-graded score, and sort the list in a descending order according to the value of the prediction error, thus filtering out the peer grades with high errors values.

The Post-Process Strategy of Score Filtering

This simple filter algorithm above may cause potential problems for the PG models. After the ScoreFilter drops these unreasonable peer-graded scores, it can create extreme cases where most peer scores for a student assignment are eliminated. In such a case, a post-processing step is necessary in the ScoreFilter to supplement new scores for the downstream PG models. For the post-processing step, we propose

Figure 4: Three Strategy to replace filtered grades.

three strategies to handle the filtered-out scores. Dropping only: The ScoreFilter simply drops the scores identified by the auto-grader and does not supplement any new scores; Replacement by Auto-Grading: The Score-Filter directly uses the grades generated by the Auto-Grader to replace the peer scores that are identified as biased; Mixed Replacement: This strategy is only designed as a contrast strategy, which can choose the replacement score for a filtered peer score among the rest peer scores and the score predicted by the auto-grader based on their absolute difference value from the ground truth. Although it is impossible to implement

this strategy in the real system, it gives us an upper-bound for the strategy design when the ground-truth is available.

Figure 4 presents the example of all the strategies. In Figure 4, the leftmost graph is the relationship between the original peer score and the real score of the submission, from left to right, the second subgraph represents the score aggregation method using the first strategy, and the third subgraph Represents the score aggregation method using the second strategy, and the last subgraph represents the using of the third strategy for score aggregation.

5. EXPERIMENTS AND RESULTS

The peer-grading experiment was conducted in the course of Computer Network, which is offered to the senior college students of the computer science major. After class, students must design a networking plan and describe device configurations in their laboratory reports. These reports are evaluated through the peer-grading process. Our experimental dataset was collected from the class sessions in Year 2015-2017, including a total of 6 peer grading assignments and 724 students and 2354 assignment reports.

5.1 The prediction accuracy of the Auto-Grader

We choose the assignment reports on the sub-networking chapter of the course as the training and test data to develop the classifier of the Auto-Grader. This sub-networking assignment consists of six problems. For each problem in the assignment, there is a rubric specifying the grading category and score scheme. Table 1 displays the categories of rubric for each problem.

Table 1: The categories of the each problem of the assignment.

Problem ID	Category 1	Category 2	Category 3	Category 4
1, 2, 3	0	5	10	—
4	0	10	20	—
5	0	10	15	20
6	0	10	—	—

In the rubrics for Problem 1-3, there are three categories and the scoring values of each category are 0, 5 and 10 points. The rubric for Problem 4 also has three categories, including 0, 10 and 20 points. The rubric for Problem 5 has 4 categories, including 0, 10, 15, and 20 points. The rubric for Problem 6 only has two categories, including 0 and 10 points. Based on the above design of rubrics, the classifier of our Auto-Grader can achieve reasonable grading accuracy. The experimental results of the Auto-Grader are shown in Table 2. The grading accuracy of the Auto-Grader classifier

Table 2: The prediction accuracy of Auto-Grader based on Naive Bayes.

Problem ID	≤ 5	≤ 10
1	66.29%	100%
2	73.6%	73.6%
3	73.03%	73.03%
4	60.11%	90.45%
5	66.85%	87.64%
6	65.73%	100%

within 5 points can achieve more than 60%, and the accuracy within 10 points becomes higher partly because of the design of the rubrics. This shows that the Auto-Grader can present reasonable score estimation as long as the threshold of the error is set to 10 points.

5.2 Choice of Post-processing Strategies for Score Filtering

We evaluate the performance of the ScoreFilter, especially the post-processing strategy. In addition to the three strategies described in Section 4.2, we also run the post-processing with the ground-truth strategy, in which the filtered top 20% peer scores are replaced by the ground-truth value. From Table 3, one can find that the Dropping-only strategy shows better performance than the Replacement by Auto-Grading strategy. The reason may be caused by the limited grading accuracy of the classifier in the Auto-Grader. Although the Mixed-Replacement strategy and the Ground-truth strategy achieve the lowest RMSE, their implementation is not feasible in the real scenario. Therefore, we have chosen the Dropping-Only strategy for post-processing in the ScoreFilter.

Table 3: The value of RMSE of Adopting the three post-processing strategies.

Post-Processing Strategy	RMSE	Post-Processing Strategy	RMSE
Dropping only	17.29	Mixed Replacement	16.45
Replacement by Auto-Grading	30.89	Only Ground Truth	15.96

5.3 Tuning the Threshold of the Score Filter

When the Naive Bayesian based auto-grader is used to each problem in an assignment submission, we need to consider the classification error of each sub-problem when we use auto-grader to evaluate the grade of each sub-problem by Eq (10).

Tuning the error thresholds

We investigated the impact of the error threshold by comparing the value of RMSE generated by the PG models and the Auto-Grader under different threshold values. The results are shown in Table 5. In Figure 5, we set the threshold

Figure 5: The trend of RMSE changes with threshold. The online labels indicate the percentage of submissions that do not have a peer score as a percentage of the total of submissions.

to filter the number of peer-graded scores with an interval of 1. We found that when the threshold is 11, the value of

RMSE drops to the lowest value, but the number of the submissions without peer grades accounts for 12% of the total submissions. In this case, the class TAs have to check these submissions and give their evaluations as the input for PG model. Therefore, when the number of assignment report is large, it will bring extra workload to the class TAs. Through our further experiments, we find optimal threshold should be 14.3, where the minimum RMSE can be calculated as 16.38, and only 3% submissions have to be assessed by the class TAs. In practice, the class instructors have to run a few rounds of peer-grading to determine the distribution of peer-grades scores and set the empirical value for the error threshold.

5.4 Overall Performance of the Hybrid Peer-Grading Framework

In order to evaluate the performance of the hybrid peer-grading framework, we run the PG models after the peer-graded scores are filtered by either the framework or random filtering respectively. In this way, we can generate three group of experimental data: the initial dataset without any score filtering, the dataset with Naive Bayesian-based Auto-Grader filtering, and the dataset with random filtering. The RMSE of the PG models based on the three data sets is shown in table 4.

After the peer-graded scores are sorted in a descending order of the estimated error, the top 20% of the scores are filtered out in each experiment. The filter process may eliminate all peer-graded scores for some submissions which have be re-evaluated by TAs. In the above experiment, when the error threshold is set to 15, 706 submissions are left with at least one peer-graded score. Only 18 submissions which account for 2% of all lose all the peer-graded scores. Thus, the task of re-evaluating these submissions does not bring too much burden to the course TAs. It can be seen from the Table 4, no matter which PG model is used, the human-machine hybrid framework can obtain the best performance, which averagely reduces the RMSE by 4. This outcome confirms that the hybrid human-machine peer-grading framework can improve prediction accuracy of the PG models with the presence of random grading behavior.

6. CONCLUSION

In this paper, we introduce a novel human-machine hybrid peer-grading framework to alleviate the problem of the random grading where student graders perform their peer-grading tasks in an undutiful manner. The most important component of the framework is the Auto-Grader that can classify

students' submissions using machine learning and enable the framework to filter out the peer-graded scores with high errors. When filtering the peer grades, the framework calculates the error threshold according to the RMSE metric. Extensive experiments confirm that the hybrid framework can effectively eliminate the noise in peer-graded scores made by undutiful student graders and improve the prediction accuracy of the PG models.

ABSTRACT

In this paper we consider the problem of modelling when students end their session in an online mathematics educational system. Being able to model this accurately will help us optimize the way content is presented and consumed. This is done by modelling the probability of an action being the last in a session, which we denote as the End-of-Session probability. We use log data from a system where students can learn mathematics through various kinds of learning materials, as well as multiple types of exercises, such that a student session can consist of many different activities. We model the End-of-Session probability by a deep recurrent neural network in order to utilize the long term temporal aspect, which we experimentally show is central for this task. Using a large scale dataset of more than 70 million student actions, we obtain an AUC of 0.81 on an unseen collection of students. Through a detailed error analysis, we observe that our model is robust across different session structures and across varying session lengths.

Educational session modelling, Student behaviour, Deep learning

1. INTRODUCTION AND RELATED WORK

Digitization of education is ever increasing, where for higher level education, massively open online course (MOOC) platforms are offering an increasing amount of high quality courses for a wide range of topics. Similarly, a wide variety of systems exist for assisting teachers in lower levels of education, where especially mathematics has been a focus since many types of exercises allow automatic correction, thus freeing up teacher resources. The design of most of these systems is that students engage with them through sessions consisting of different actions, e.g. answering questions or reading learning material, but the frequency and length of sessions naturally vary between students.

In this paper we consider the problem of modelling when an action is the last action in a session, which we denote as the End-of-Session action. This is naturally a highly class imbalanced problem, since there is only one End-of-Session action per session, and we do not get any explicit feedback about the student's intent to end a session before it is over. Additionally, a large amount of external and internal factors for ending a session exists, for example: The student has finished an assigned task (e.g. homework), the student is unmotivated or distracted, the student has grasped the material, etc. If we are able to model the End-of-Session probability for each action accurately, then it can offer real-time insights in ongoing student sessions, and actions can be taken to steer the student in a direction where she is less likely to quit.

The problem of modelling when a session ends has, to the best of our knowledge, only recently been considered by Kasak et al. [8] in the educational domain, where a polynomial classification model with handcrafted features was used, but the work was done on a small scale using just 452,000 student actions. Related work to this problem has also been considered from the point of view of modelling and clustering student sessions, in order to understand and group student behaviour in educational systems [11, 5, 9]. Even though the End-of-Session problem has not been investigated much in the educational domain, the problem has been considered in other domains, such as business [13] and media streaming [14, 3], where recurrent neural networks and gradient boosted trees have been shown to work well.

A related problem to End-of-Session modelling that has been considered extensively in the educational domain, is drop-out prediction. In this setting student log data is used for modelling drop-out of students, with studies focusing on whether a student will drop out of their studies [1], or drop out of MOOC courses [2, 10, 15]. Drop-out prediction models can utilize both general characteristics of a student, as well as usage behaviour changes (e.g. usage decline) to aid in the prediction. Although End-of-Session modelling utilizes much of the same types of data, in this setting the "stop"-signal needs to be found within each session, and not as a single terminal event happening at a single point.

In this paper we model the End-of-Session problem using a deep recurrent neural network architecture, that outputs an End-of-Session probability for each student action, using the actions in the current and previously completed sessions.

Christian Hansen, Casper Hansen, Stephen Alstrup and Christina Lioma "Modelling End-of-Session Actions in Educational Systems" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 306 - 311

We show that considering the task on a studentwise level obtains significant improvements over considering the sessions individually. We experimentally evaluate our approach using log data from more than 70 million student actions from 85,780 students, where we are able to obtain an AUC score of 0.81 on an unseen collection of students. Through a detailed error analysis we show that the model is robust across students with a varying number of completed sessions, across sessions of different lengths, as well as for different session structures.

In the remaining of the paper the data is presented in Section 2; the End-of-Session problem is presented in Section 3, and our deep learning approach presented in Section 3.1; experimental findings are presented and analyzed in Section 4; and a conclusion is made in Section 5.

2. DATA

In this paper we use data provided by Edulab¹, the largest Danish system for online mathematics. The system primarily targets students aged 6 to 16 and supplies material spanning the entire mathematics curriculum. The system offers two primary ways of engaging with the material: 1) Reading text material or watching video material, and 2) answer fill-out or multiple-choice questions. These two broad categories can be done by students on their own initiative or by being assigned it as homework by a teacher. All questions and video/text materials are associated with a specific *lesson*, which is a specific skill such as "addition of small integers", and each lesson is associated with a *topic*, which is a broad skill such as "addition". The general data statistics can be seen in Table 2.

We use log data generated when students use the system. For each action they perform we have the timestamp, the lesson id, the topic id, the type of action (and an answer if the action is answering a question), and lastly whether it is homework. The system does not track the exact time taken to complete an action, but can derive it as the time taken since the last action. To group the actions into sessions, we consider a time gap of more than 15 minutes to be a new session. The choice of 15 minutes was based on each action rarely requiring more than a few minutes, and to allow time for breaks within the same session. From these we derive a set of general features associated with each action as described in Table 1. For the temporal features we chose to discretize the time into the time intervals 8-12, 12-15, and 15-8 in order to represent the times as "before noon", "afternoon", and "after school". For content type we decided to ignore the actual ids, and instead focus on the changing between lessons and topics. The reason for this was the large number of different ids, with close to 1000 different lesson ids. This also has the benefit of being more general, since the system will not be able to learn patterns specific to certain ids.

There is a large variance in the number of sessions each student has completed and the length of each of the sessions, the histograms for each of these can be seen in Figure 1 and 2 respectively. For the histogram of session lengths, spikes are seen at certain lengths divisible by 5, this is due to how

¹The data is proprietary and not publicly available.

Category	Features
Temporal	1) time of day as discrete values 8-12, 12-15, and 15-8, 2) time since last action, and 3) time since last session.
Action type	1) answering fill-out question, 2) answering multiple-choice question, and 3) watching or reading material.
Content type	1) the lesson id was changed compared to the previous action, and 2) the topic id was changed compared to the previous action.
Miscellaneous	1) whether a potential question is answered correctly, and 2) if the action was done as homework or on the student's own initiative.

Table 1: Dataset features divided into categories.

Number of students	85,780
Number of sessions	2,587,876
Number of actions	71,341,770
Percentage of sessions being homework	48.3%
Percentage of sessions being partly homework	25.5%
Percentage of sessions not being homework	26.2%

Table 2: General data statistics.

some groups of questions are presented to the students, e.g. as 5 or 10 quick related questions. Similarly, homework often consists of a number of questions divisible by 5.

3. MODELLING END-OF-SESSION

In this section we present the problem of modelling when a session ends, by predicting the probability of a certain action being the last in the current session, which we denote as the End-of-Session action. A session consists of a number of actions being either reading or watching some material M or answering a question Q , for example:

$$M \rightarrow M_{\text{lesson changed}} \rightarrow M_{\text{lesson changed}}^{\text{topic changed}} \rightarrow \quad (1)$$

$$Q \rightarrow Q \rightarrow Q_{\text{lesson changed}} \rightarrow M$$

where the sub- and superscript denote if the lesson or topic id was changed compared to the previous action. To each of these actions we associate a binary label indicating whether or not the action is the last action in the session. We consider this binary label a probability of an End-of-Session action, such that the last action has a probability of 100% for ending the session and all the previous ones have 0%. Naturally, this leads to a very imbalanced dataset. The goal of this task is to create a model able to assign a probability score to each action indicating its End-of-Session probability, and such that it is largest at the true End-of-Session action.

Usage of the Edulab system is very non-restrictive. A student can engage in any material she wants, and can choose to do the assigned homework at any time. Due to this it is inherently individual how each student uses the system, and when they end their session. It is therefore relevant to consider the problem on a student level, as students have their own preferences with regards to session length, and consequently when the End-of-Session action occurs. This kind of individual behaviour does not only define the general length of student session, but can also influence the dynam-

Figure 1: The distribution of sessions per student.

ics between sessions, since e.g. some students may prefer to alternate between longer and shorter sessions; or take a quick repetition session the next time they engage with the system.

3.1 Deep Learning Approach

We propose to use a deep learning approach utilizing a recurrent neural network (RNN) for modelling the End-of-Session problem. This approach has the benefit of not requiring complex feature engineering, and is able to capture complex temporal representations of student behaviour. Certain behaviour patterns may occur at a much earlier point than the current action, so to this end we choose to use a Long Short Term Memory (LSTM) network [7].

Our proposed network architecture is displayed in Figure 3, and can be considered in 4 parts:

- **Actions:** The input to the network are the actions associated with each student. During training each action is labeled either 0 or 1, depending on whether the action is the last in a session. The actions are passed as one long sequence. Each session within this sequence is identifiable by the network through the "time since last session" feature, as well as if the previous label was equal 1, in which case the next action must be a new session.
- **Memory:** The purpose of the memory layer is to let the current interaction's effect on the End-of-Session probability be influenced by previous actions and learned student characteristics. As mentioned previously, we use a LSTM unit for this task, which is able to handle long dependencies in the sequential data, and suffer fewer problems related to vanishing gradients.
- **Fine tuning:** The output of the memory layer is passed to the fine tuning block consisting of two fully connected layers with ReLU activation. The purpose of this is to refine the output of the LSTM, such that the LSTM is able to focus on learning the general underlying behaviour of a student.
- **Prediction:** The fine tuned output is passed to a single neuron with a sigmoid activation. The sigmoid function returns an output between 0 and 1, representing the End-of-Session probability.

Figure 2: The distribution of session lengths.

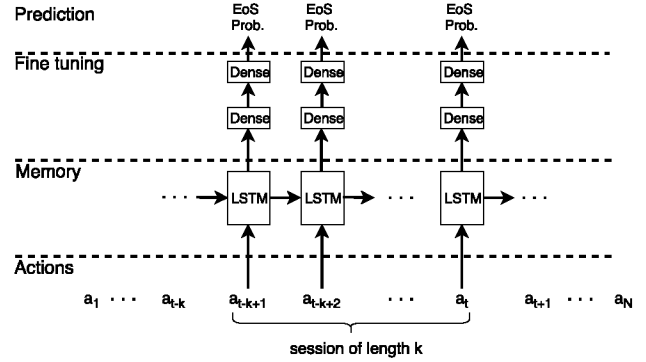

Figure 3: Network architecture of our model.

Between all layers we use Dropout [12], which sets the activation of a neuron to zero with a certain probability, and is used to limit the network's ability to overfit.

3.2 Parameters and training

For the number of neurons in each layer we use a fan-in approach, where the size is halved from each adjacent layer to the next. Due to the training time of the network, extensive tuning of the dropout probability p and layer sizes is beyond the scope of this paper, but initial experiments showed that $p = 0.4$ performed well, which is within the typical range of 0.2 to 0.5 [12]. For the layer sizes, initial experiments showed that a LSTM size of 400 performed well, leading to the fine tuning layers having size 200 and 100 respectively.

We train the network using the RMSprop optimizer with a learning rate of 0.001, and use binary cross entropy as the loss function. Due to the End-of-Session problem being heavily class imbalanced, we do a studentwise re-weighting such that if a student has 400 actions consisting of 16 sessions, then each End-of-Session action is weighted by 25, while the others have a weight of 1. This forces the network to balance its ability to predict both normal and End-of-Session actions. This re-weighting changes from student to student based on each student's average session length.

3.3 Session level model

In the previous section we presented our approach for modelling the End-of-Session probability by utilizing the full history of past actions for each student. As a baseline approach

we can use the same model architecture, but do the modelling on a session level, using just the past actions in the current session, instead of on a student level as before. This will show the benefit of personalizing the model, instead of just focusing on each individual session alone.

4. EXPERIMENTAL EVALUATION

In this section we will describe the experimental evaluation and error analysis of our approach. Our experimental performance comparison is between the performance of the student level model versus the session level model, in order to quantify to what degree a session is self-explanatory with regards to its length, and whether learning a student representation is beneficial. Based on this we analyze the student level model in the following ways:

1. We investigate how the End-of-Session probabilities associated with each action increases or decreases throughout a session.
2. We investigate how homework sessions influence the model's performance, since these can be considered fixed compared to when students use the system on their own initiative.
3. We consider how the model performs for sessions of varied length, in order to investigate the necessary session length for the model to perform well.
4. We consider how the model performs on students with limited system usage, i.e. when considering students with a varying number of sessions, in order to investigate how many sessions are needed for this task.

4.1 Experimental Setup

We split the students in our dataset randomly into a training set, validation set, and testing set. We use 90% of the students for training and the remaining 10% for testing. For validation 10% of the students from the training data are used. Thus, the students validated and tested on have not been seen previously during training. For training the network we use a batch size of 64, and employ early stopping with a patience of 3, i.e. we use the model with the best validation performance, and stop after no improvements have been seen in 3 epochs. We use the same approach for training the session level model, where the sessions are extracted from the students in each of the sets.

For measuring the performance we use the area under the receiver operator characteristic curve (AUC). The reason for this is that we do not require the predicted End-of-Session probabilities to be either 0 or 1 (as their labels), but rather expect them to increase slightly over time, with a large increase in the close proximity of the End-of-Session action. Since the sessions are of vastly varied lengths (see Figure 2), we argue that this measure is very useful, since it handles the class imbalance, and most importantly provides a measure for how we are able to rank normal and End-of-Session probabilities compared to each other across all students.

4.2 Model Performance

In section 3.1 we presented two models: The first being the student level model where we used all previous actions when

Model	AUC
Student level model	0.8103
Session level model	0.5647

Table 3: AUC scores of the student and session level model.

Figure 4: Average End-of-Session probability for sessions split into 5% chunks, done for sessions with at least 20 actions.

predicting the End-of-Session probability of an action, and the second being the session level model where we considered each session alone. We do not expect the session level model to perform as well as the student level model, but this comparison will show to what extent a student's current behaviour can be described by just the current session. Table 3 displays the AUC scores for each of the models. The student level model significantly outperforms the session level model (AUC of 0.8103 vs 0.5647 respectively), showing the importance of modelling the student.

We will now consider how the End-of-Session probabilities associated with each action increase or decrease throughout a session. To do this we consider all sessions with at least 20 actions, and cut each session into intervals consisting of 5% of the actions. This means that each interval for a session with length 20 consists of 1 action, while one of length 100 has 5 actions in each interval. For each of these intervals we compute the average End-of-Session probability. We do this for all sessions and plot the average End-of-Session probabilities for each of the intervals in Figure 4.

Surprisingly, we observe that the End-of-Session probability is relatively large in the beginning of a session, most notably in the first interval, but also in the second compared to the third. The reason for this is most likely the large amount of short sessions in the dataset (see Figure 2), such that the model learns that a student is likely to quit relatively fast. These short sessions could have been removed, but we wanted to base the model on the full history of sessions, and not with artificial session gaps.

When the model observes that the session has not ended very early, the End-of-Session probability drops, and a small gradual increase is seen until the 95% interval. In the last interval the End-of-Session probability increases relatively

Sessions consisting of:	AUC
Only homework	0.8228
Partly homework	0.8214
No homework	0.7800

Table 4: The AUC scores of actions in sessions consisting of only homework, partly homework, or no homework actions.

quickly, compared to the gradual increase observed from 10% to 95%. The true End-of-Session action has an average probability of 65.7%. Even though the true End-of-Session action should ideally have a probability closer to 100%, it is still significantly larger than earlier action’s End-of-Session probabilities, which means we are able to create a ranking useful for measuring when a session is likely to end.

4.3 Further analysis

We conduct a further analysis of the model focusing on how the performance varies when considering: 1) sessions with varying degree of homework, 2) sessions with varying length, and 3) students with varying number of sessions.

4.3.1 Homework sessions

As described in Section 2 students are assigned homework through the Edulab system, where, as seen in Table 2, 48.3% of all sessions consist purely of homework. Sessions consisting of partly homework or no homework are at 25.5% and 26.2% respectively. We consider how the model performs in each of the three cases, where the AUC scores can be seen in Table 4.

Sessions consisting of pure homework can be considered fixed in the sense that a teacher has decided their exact content. Thus, one could imagine the general behaviour of a student to be of lesser importance, since a student is just completing the assigned task. However, if a student is likely to quit early, or split the homework into multiple sessions, then previous observed behaviour is still valuable. The AUC score of all sessions in this case is 0.8228, which is marginally larger than the global AUC score of 0.8103, and thus shows this case to be slightly easier to predict. Sessions consisting partly of homework obtain a similar AUC score of 0.8214. This shows that sessions with fewer individual choices are easier to model (unlike sessions without any constraints).

Sessions consisting of no homework, thus only of actions decided by the student, obtain an AUC score of 0.78, thus lower than the global AUC. This follows our intuition and previous observations, since these should be more difficult, as it is entirely up to the student to define their own task and amount of time they spend using the system.

4.3.2 Sessions of varying length

In this section we consider how the model performs on sessions of varying length, where AUC scores across intervals of session lengths can be seen in Table 5. We see that the model is less accurate when modelling very short sessions of length 1-5 (0.6156 AUC), but from lengths 11 and upwards an AUC of 0.80 ± 0.02 is obtained. That the model performs worse on very short sessions is to be expected, since a certain amount of actions are needed to infer the student’s current behaviour. Additionally, we observed in Section 4.2 that

Session length interval	AUC
1-5	0.6156
6-10	0.7604
11-20	0.7859
21-30	0.8200
31-40	0.8060
41-50	0.8333
51-60	0.8109
61-70	0.8088
71-80	0.8157
81-90	0.8103
91-max	0.8016
Divisible by 5	0.8944
Not divisible by 5	0.7568

Table 5: The AUC scores of actions in sessions of varying length, grouped in small intervals. E.g. 6-10 corresponds to actions associated with sessions of length 6 to 10.

the model had a tendency to initially predict large End-of-Session probabilities for all actions, which also explains why the model generally performs poorly for very short sessions.

A large part of the Edulab content is presented by groupings of related questions, e.g. as 5 or 10 quick questions, and the number of assigned homework questions are often divisible by 5 as well. Due to this a large part of the sessions have lengths divisible by 5, and the model should be able to detect and adapt to when these kind of patterns occur. In Table 5 we see that the AUC score of those sessions are 0.8944, which is significantly larger than the global AUC, thus showing that the model is indeed able to detect these patterns. In the case of less structured sessions, i.e. those of lengths not divisible by 5, we obtain a significantly lower AUC of 0.7568. These trends are similar to those observed when considering the amount of homework a session consisted of, and shows that while the model is more accurate when structure is present, it is also able to adapt and provide reasonably high AUC scores in the unstructured case.

4.3.3 Students with varying number of sessions

We consider how the model performs for students with varying system usage, i.e. who has completed a varying number of sessions. In Table 6 we generally see that actions associated with students with more sessions are more accurately predicted, since the intervals of those with more completed sessions obtain larger AUC scores. This shows that the network is able to learn student specific characteristics which are helpful for the task of predicting End-of-Session.

5. CONCLUSION

We presented the problem of determining when a session ends, by modelling the probability of an action being the last in its session, which we denoted as the End-of-Session probability. This problem is difficult to model since we do not get any explicit information about a student’s intent to end a session soon, but only in the action it happens. Additionally, a multitude of reasons for the session ending exist, e.g. by a student finishing an assigned homework task, feeling unmotivated, or when the student has mastered the material. To model this problem we proposed a deep recurrent neural

Student session interval	AUC
1-5	0.7799
6-10	0.7866
11-20	0.7938
21-30	0.8022
31-40	0.8054
41-50	0.8123
51-60	0.8218
61-70	0.8236
71-80	0.8221
81-90	0.8256
91-max	0.8153

Table 6: The AUC scores of actions in sessions of students with varying number of total sessions, grouped in small intervals. E.g. 6-10 corresponds to students with between 6 to 10 completed sessions.

network architecture, that predicts the End-of-Session probability for each student action, by incorporating information from past actions in the current and previous sessions. We consider this a student level model, and for comparison we created a similar session level model, where only the actions associated with a given session were used, and not all previous actions as in the student level model. The student level model obtained an AUC of 0.8103 and the session level model an AUC of 0.5647, thus showing the benefit of learning the student behaviour for this task. Through a detailed error analysis we showed that our model is robust across sessions of different lengths, except for very short sessions of 1 to 5 actions. Similarly, the model gets progressively better for students with more completed sessions, but even with just 1 to 5 sessions an AUC of 0.7799 was obtained. Lastly, the model performed better in sessions with a known structure (e.g. homework), but it was still able to adapt and perform well in sessions where the students chose the content on their own.

In the future we will apply our model, to obtain real-time insights into how the End-of-Session probability progresses throughout sessions and student skill evolution [6]. Additionally, we will combine this problem with Knowledge Tracing, where relatively simple temporal features have already shown to increase performance [16]. In terms of modelling, we will explore more elaborate RNN extensions that have been shown to work well with various sequence-based data [3, 4].

ABSTRACT

Students' questions categorization is a challenging task as the available corpora are often limited in size (particularly with languages other than English) and require a costly preliminary manual annotation to train the classifiers. Ensemble learning can help improve machine learning results by combining several models, and is particularly efficient to leverage the strengths of very different classifiers. In this paper, we investigate how combining a rule-based annotator (based on keywords identified by an expert) with various machine learning-based approaches and TF-IDF can improve the automated identification of questions asked by 1st year medicine students on an online platform, according to a coding scheme using 4 dimensions. First we evaluated the performance of several models, calculating the kappa between the prediction and the manually labelled dataset, according to each dimension. Then, using a stacking approach, we tried different combinations of them to design a predictive model with a higher performance. The results reveal that the new ensemble models can help to increase the performance for all dimensions of the dataset, in particular those for which the expert rule-based system showed the lowest performance. These results are promising as they indicate that some easy-to-train models can complement more manual approaches, even with a small training set of a few hundreds of annotated questions.

Keywords

Student's question, ensemble learning, stacking, coding scheme, hybrid method, question categorization

1. INTRODUCTION

Categorizing students' questions with limited size of corpora remains a challenging task. The available classification methods require a costly preliminary manual annotation to obtain labeled data, and it is tempting to try training many different classifiers in the hope that combining their predictions would give good performance. One of the most active

areas in machine learning has been in studying methods to build good ensembles of classifiers [3]. The premise that ensembles are often much more accurate than the individual classifiers make them more attractive. Ensemble learning helps improve machine learning by combining several models to obtain an overall classifier which prediction accuracy outperforms every single one of them [7, 9]. Among the existing ensemble approaches, stacking [17] is often used. It consists in training a combining classifier (sometimes called a meta-classifier), in addition to the set of individual classifiers, which takes as input the output of the other classifiers.

In this paper, we used a pre-existing coding scheme to annotate students' questions asked by 1st year medicine students on an online platform, and investigated different approaches to improve the automated identification of their questions. We used the stacking approach by combining heterogeneous classifiers such as a rule-based annotator with various machine learning-based approaches and TF-IDF. Our goal was to answer to two research questions: (RQ1) Can combining different approaches improve the performance of the predictive model? (RQ2) What is the best combination of families of classifiers, and in particular, can a hybrid system (mixing expert rules and machine learning) be relevant?

2. STATE OF THE ART

Annotating a corpus automatically requires using a coding scheme or a taxonomy of sentences, messages or speech acts. Many taxonomies have been used to characterize the types of questions that students ask. Graesser and Person [4] developed a taxonomy of questions asked during tutoring sessions according to the level of thought. Another well-known taxonomy widely used in education, the Bloom's taxonomy [2] and its revisions [1], was originally created in order to help teachers in formulating questions and therefore tends to be more appropriate for teachers' questions (*e.g.* assessment) than for students' ones. The questions coding scheme used here was defined based on the corpus at hand to match them more accurately, even if some overlap exists with categories of existing taxonomies.

Ensemble learning has been investigated in many studies [11, 10] and consists in weighting several individual classifiers, and combining them in order to obtain a classifier that outperforms every single one of them considered separately. First, different classifiers are generated by training models on different features from the training set. The generated

Fatima Harrak, François Bouchet and Vanda Luengo "Categorizing students' questions using an ensemble hybrid approach" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 312 - 317

classifiers are then typically combined by some form of majority or weighted voting. In this work, we do not restrict how the individual classifiers are trained, but we deal with different models and not only probabilistic ones which is a prerequisite for some of these techniques.

The stacking framework introduced by [17], consists in combining multiple classifiers models created by using different learning algorithms on a single dataset. Several variations of this idea have been attempted. Ting and Witten stacked base-level classifiers whose predictions are probability distributions over the set of class values, rather than single class values. The meta-level attributes are thus the probabilities of each of the class values returned by each of the base-level classifiers. Multi-response linear regression, an adaptation of linear regression, is recommended for meta-level learning to predict binary variables [15]. Merz [8] proposed a stacking method called SCANN that uses correspondence analysis to detect correlations between the predictions of base-level classifiers. Todorovski and Dzeroski [16] introduced a new meta-level learning method for combining classifiers with stacking: meta decision trees have base-level classifiers in the leaves, instead of class-value predictions. Researchers in [14] presented a novel bayesian model that relies on combining different models in order to improve the classifier accuracy.

In this paper, we investigated how combining heterogeneous classifiers (derived by different learning algorithms, using different model representations) can help to improve the automated identification of questions using a stacking approach.

3. CONTEXT

The dataset considered in this paper is made of questions asked in 2012 by 1st year medicine/pharmacy students from a major public French university. The Faculty of Medicine and Pharmacy has a specific hybrid training system (reading of the material for the class is done at home, and classroom time is dedicated mostly to Q&A) for their 1st year students. The 1st year is divided into two semesters, each of them ending with a competitive exam (in January and May) on the content studied during the period: only a predefined number of students is allowed to continue in the second year. Between the reading session at home and the classroom session, the students can connect to an online platform to either ask a question, or see questions asked by other students and vote for them if they also want an answer to that question. They cannot however propose an answer to those questions. Then, the questions asked online are sent to teachers to help them prepare their Q&A session. The dataset contains 6457 questions overall asked by 429 students.

4. QUESTION CODING SCHEME

We chose to consider the nature of questions as defined in the coding scheme introduced in [5], in a process involving multiple human coders and several refinement phases. This coding scheme (summarized in Table 1) consists in tagging each question according to 4 independent dimensions: a main one (dimension 1), which is mandatory, and 3 optional ones (dimensions 2 to 4 - cf. Table 1 for the corresponding definition of each dimension). For instance, a question could be a request to re-explain the way something work by providing another example (tagged as Ree (1) on dimension 1,

Table 1: Coding scheme

ID	Dim1	Question type	Description
1	Ree	Re-explain / re-define	Ask for an explanation already done in the course material
2	Dee	Deepen a concept	Broaden a knowledge, clarify an ambiguity or request for a better understanding
3	Ver	Validation / verification	Verify or validate a formulated hypothesis
ID	Dim2	Explanation modality / Quest. subject	Description
1	Exa	Example	Example application (course/exercise)
2	Sch	Schema	Schema application or an explanation about it
3	Cor	Correction	Correction of an exercise in course/exam
ID	Dim3	Explanation type	Description
1	Def	Define	Define a concept or term
2	Man	Manner (how?)	The manner how to proceed
3	Rea	Reason (why?)	Ask for the reason
4	Rol	Roles (utility?)	What's the use/function
5	Lin	Link between concepts	Verify a link between two concepts, define it
ID	Dim4	Verification type (optional)	Description
1	Mis	Mistake / contradiction	Detect mistake/contradiction in course or explanation of teacher
2	Kno	Knowledge in course	Verify knowledge
3	Exp	Expected knowledge	Verify expected information in exam or quiz (assessment)

Exa (1) on dimension 2, Man (2) on dimension 3, and nothing (0) on dimension 4, *i.e.* represented as the dimension vector [1,1,2,0]). It could also be a request to verify (Ver = 3) if a schema (Sch = 2) needs to be known for the final exam (Exp = 3) (which would be tagged as [3, 2, 0, 3]). We considered here a corpus of 923 questions manually annotated according to the 4 dimensions of the coding scheme for training and testing the automated annotators. A subsample of 723 questions was used for training the classifiers, and 200 questions were used to test their performance.

5. AUTOMATED ANNOTATORS

5.1 Approach 1: expert rule-based annotator

We used first a previously developed custom annotator relying on keywords manually identified and associating them a weight [6]. To design it, the human annotator identified from a separate dataset of questions in the corpus the keywords that were indicative of each dimension value (*e.g.* in Dimension1, for the dimension value "Re-explain", some of the keywords identified were "re-explain", "restate", "redefine", "retry", "repeat", "revise", "get back on", *etc.*). For each question, for each dimension, the question was tagged in the dimension according to the value that had the highest number of keywords associated to it (*e.g.* for dimension 1, a question with two keywords associated to the value "re-

Table 2: Kappa between the standalone expert rule-based annotator and the reference manual annotation

Dim1	Dim2	Dim3	Dim4
0.76	0.69	0.70	0.65

explain” and one keyword associated to the value ”validation” would be tagged as a ”re-explain” question).

The automatic annotator is using a set of weights associated to each keyword of each dimension (*e.g.* ”explain”: 7, ”what/how”: 3), and defined using the set of 723 questions. Those weights were determined in two steps: first, the human annotators empirically associated a weight between 1 and 9 to each keyword, depending on whether they thought they were very marginally (1), significantly (5) or very significantly (9) associated to a given dimension. Then in a second step, the automatic annotator was used on the 723 manually annotated questions, and weights were manually adjusted (adding or removing 1) on some keywords for questions for which the manual and automatic annotation were different, iterating until full agreement was obtained on almost all segments from the 723 questions. Finally, the question identified by the values associated to each dimension, is represented as a dimension vector.

The Kappa values per dimension for the annotations coming from human expert and the automatic annotator are given in Table 2.

5.2 Statistical approaches

5.2.1 Data coding: from questions to words vectors

First, we used the French version of WordNet [12], a lexical database linking semantic concepts to each other in an ontology according to a variety of semantic relations (*e.g.* synonyms and hyperonyms). The aim was to transform different synonyms into the same expression in the questions (*e.g.* for dimension value ”Reason” in Dim3, the synonym words ”cause”, ”reason” and ”motif” were replaced in the text by ”why”) to reduce the lexical diversity and consolidate a particular expression for the following treatment. Then, the classical preprocessing steps are used on the corpus of 923 questions: punctuation removal, stemming, tokenization, and stopwords filtering. After extracting the unigrams and bigrams for all questions in the corpus, the weights for the words are computed using two different methods: (1) TF-IDF (described in the next section), (2) counting occurrences (’1’ if the word is in the question, ’0’ otherwise). Each of the 723 questions was represented by a word vector according to (1) or (2). We finally reduced the number of extracted keywords to keep the most important and significant ones using a feature selection technique (removing less frequent and correlated unigrams and bigrams).

5.2.2 Approach 2: TF-IDF

We used TF-IDF [13] to compute term weights. The goal of TF-IDF is to estimate how the words in a given document are representative of that document when compared to a larger set of documents. It combines two complementary metrics: the term frequency (TF), and the invert document

frequency (IDF). TF thus gives a higher weight to the commonly occurring terms and a lower weight to rare terms. The drawback is that some words that are common in a given document but also common in all documents could end up with a weight that is over-representing their real importance. IDF fixes this issue by adjusting the weight with the general importance of the term. Equation 1 describes the method to compute individual TF-IDF weight values for each term (word). We made two different calculation measures of TF-IDF on the corpus of 723 questions.

$$W_{ik} = TF_{ik} \cdot \log \left(\frac{N}{n_k} \right) \quad (1)$$

Where:

W_{ik} = TF-IDF weight for term k in document Q_i

TF_{ik} = frequency of term k in document Q_i

IDF_{ik} = inverse document frequency of term k in document $Q_i = \log \left(\frac{N}{n_k} \right)$

N = total number of documents in the questions corpus

n_k = number of documents in the corpus that contain the term k

The first version consists in calculating four separate TF-IDF on each of the four dimensions, to extract the words that differentiate each category on each dimension. For a given dimension, all the questions manually annotated in each category (*e.g.* ”Re-explain”) were considered as documents (*e.g.* on dimension 1, document1 is the union of questions annotated as ”Ree”). Each document (set of questions) is converted into a corresponding word-weight vector, where each word-weight represents the TF-IDF measure for the word in the document. TF-IDF weight (W_{ik}) was attributed for each term k in document i (i is the number of documents in that dimension, *e.g.* i varying from 1 to 3 for dimension 1). In order to classify new questions, we used the TF-IDF weights calculated on each dimension value from the sample of 723 questions. We attributed TF-IDF weights calculated on the training sample for the corresponding words on the test sample of 200 questions. Then, we chose the simplest ranking function which consists in summing the TF-IDF weights for each question on each dimension value. Therefore, for each question, for each dimension, we tag the question in that dimension according to the value that has the maximum weights. Finally, we calculated the Kappa values between the values found by this model [**TF-IDF+MAX**] for that dimension, and the corresponding values found by the manual annotation (*cf.* first column of Table 3). Two versions were tested: one where the questions were preprocessed using WordNet (*cf.* previous section) and one where they were not. The results obtained were similar in terms of performance, so we decided to keep the version including the preprocessing with WordNet, as it intuitively should generalize better to variations of existing questions.

In the second version, TF-IDF was calculated on the corpus of 723 questions without distinguishing the different dimensions. The questions were not grouped by dimension value, but instead, each question in the corpus was considered as a document (*i.e.* 723 documents overall). The document

Table 3: Kappa between automatic annotation obtained by standalone TF-IDF + different ML methods and the reference manual annotation

Dim.	TFIDF +						
	Max	GLM	GBT	NB	KNN	DT	RI
Dim1	0.66	0.69	0.71	0.47	0.62	0.46	0.61
Dim2	0.39	0.73	0.69	0.12	0.56	0.49	0.36
Dim3	0.66	0.59	0.60	0.43	0.58	0.37	0.52
Dim4	0.58	0.71	0.63	0.37	0.60	0.19	0

is then converted into a corresponding word-weight vector, where each word-weight represents the TF-IDF measure for the word in the question. Finally, we used the word vectors as the input for machine learning techniques to predict the value associated to the question in that dimension (described in section 5.2.3).

5.2.3 Approach 3: ML-based annotator

We tried 6 machine learning (ML) classification techniques (Generalized Linear Model [GLM], Gradient Boosted Trees [GBT], Decision Tree [DT], K Nearest Neighbors [K-NN], Rule Induction [RI] and Naïve Bayes [NB]) for each dimension separately. The appropriate hyper-parameters (such as k for K-NN) were chosen in each case to obtain the highest value and may differ from one table to another. For each classifier, the input was the word vectors and the label to predict was the value associated to the question in that dimension. We considered the corpus of 923 questions as labeled data. Then, we trained the classifiers on the 723 questions and evaluated their performance on an independent sample of 200 questions, to ensure a good estimation of the performance on unseen data. Finally, we calculated the Kappa values between the values found by the classification model for that dimension, and the corresponding values found by the manual annotation. We considered two versions for comparison here as well: the first one using the corpus processed using WordNet, and the second one without the processing with WordNet.

5.3 Results

The kappa values found with the three automated annotators taken individually (expert rule-based, TF-IDF and ML) are provided in Tables 2, 3 and 4 respectively for each dimension. We note that the expert rule-based annotator clearly outperforms both ML-based annotator and TF-IDF only on dimension 1, whereas they almost have similar performances on dimension 3. TF-IDF with the classifier GLM gives the best performance on dimension 4. Furthermore, the ML-based annotation without WordNet performs better than the classifiers using WordNet for all dimensions and particularly on dimension 2.

6. ENSEMBLE HYBRID APPROACH

Our next step consists in building a predictive model with a higher performance to improve the automated identification of questions according to the coding scheme provided in Table 1. Using the aforementioned stacking approach, we tried different combinations of models regardless of which classifier is the best one. Moreover, it does not require any of the classifiers to be probabilistic; they can even be human experts. Our goal was not only to obtain the best classifier

Table 4: Kappa between automatic annotation obtained by standalone different ML methods and the reference manual annotation

Dim4	0.63	0.67	0.46	0.59	0.10	0.47

performance, but also to do so using a fairly small training set of annotated questions and see if a good performance could be obtained nonetheless.

6.1 Method for stacking

In the first phase, a set of 20 base-level models have been created (1 expert rule-based annotation, 7 TF-IDF annotation and 12 ML-based annotation). In this second phase, we want to train a meta-level classifier that combines the outputs of the base-level models. In other words, we have 20 predictions for each dimension for each of the 200 question segments in the testing set, as well as the 20 manual annotations for these 200 segments that provide a grounded truth, and we want to train a classification model using some subsets of these 20 features. We trained the meta-level classifier using the same aforementioned 6 classification techniques (GBT, GLM, NB, K-NN, DT, and RI) for each dimension separately, using a 10-fold cross validation to ensure a good estimation of the performance (*i.e.* training the models on 180 segments and testing on 20). Finally, for each model we calculated the Kappa values between the values found by that meta-model for that dimension, and the corresponding values found by the manual annotation. Regarding the set of features we considered, we wanted to consider combinations that mixed different set of approaches, and we therefore considered six meta-learning combinations described below. For each of them, the training was performed four times (once for each of the four dimensions - *cf.* Figure 1).

(1) Stacked TF-IDF models: We combined the outputs of the methods using each individual TF-IDF classifier to compute keywords weights (*i.e.* 7 features for each classifier, *cf.* Table 3).

(2) Stacking TF-IDF with expert rule-based annotation: We combined the outputs of the TF-IDF models with the output of the expert rule-based annotator (*i.e.* 8 features for each classifier, *cf.* Tables 3 and 2).

(3) Stacked ML techniques: We combined the outputs of the machine learning-based annotation with the two combinations: processing using WordNet and without it (*i.e.* 12 features for each classifier, *cf.* Table 4).

(4) Stacking ML techniques with expert rule-based annotation: We combined the outputs of the machine learning-based annotation (with and without WordNet) with

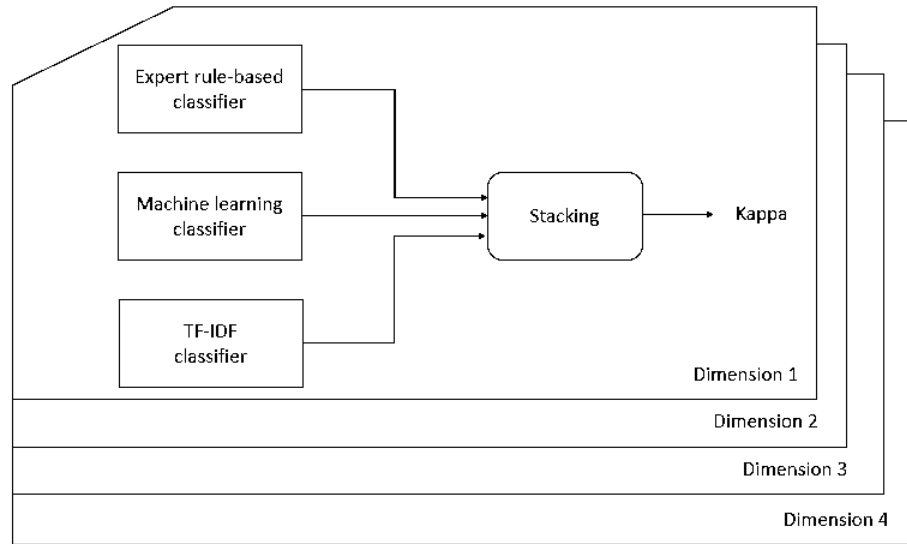

Figure 1: The overall stacking process

the output of the expert rule-based annotation (*i.e.* 13 features for each classifier, *cf.* Tables 4 and 2).

(5) Stacking ML techniques with TF-IDF: We combined the outputs of the machine learning-based annotation (with and without WordNet) with the output of TF-IDF based annotation (*i.e.* 19 features for each classifier, *cf.* Tables 4 and 3).

(6) Stacking ML, TF-IDF and expert rule-based annotation: We combined the outputs of all the existing classifiers: the machine learning-based annotation (with and without WordNet) with the output of TF-IDF and expert rule-based annotation (*i.e.* 20 features for each classifier, *cf.* Tables 4, 3 and 2).

6.2 Results and discussion

The kappa values found with the 6 classification techniques for each dimension are provided in Table 5. Each stacking model was trained individually on each dimension and the highest value obtained for each dimension among the 6 classifiers is tagged in bold, for each set of features considered. For instance, on the first row, we see that when combining the 7 TF-IDF classifiers that predict dimension 1, the best stacking result is obtained with a decision tree (0.75), which outperforms the best individual TF-IDF classifier (0.71 with GBT, *cf.* Table 3). We can notice that Naive Bayes is often the best ensemble classifier among the 6 tested, giving better performance on a small dataset. The best overall performance between the 6 set of comparisons are marked with a star (*): for dimension 1 and 4, it is Naive Bayes combining the ML and the expert rule-based classifiers, for dimension 2 it is Naive Bayes combining TF-IDF and the expert rule-based classifiers, and for dimension 3 it is GBT combining also TF-IDF and the expert rule-based classifiers.

When considering the combinations involving TF-IDF, we see that the combination of several TF-IDF outperforms the

base-level TF-IDF on dimension 1 and 3. The kappa values are overall lower on dimensions 2 and 4, which is probably due to the unbalanced training data in these dimensions (it also explains why sometimes a classifier would obtain a kappa of 0 on these dimensions in the various tables). Moreover, the various TF-IDF classifiers combined with expert-rule based annotator outperforms both the TF-IDF base-level and expert-rule based annotator, as well as the combination of several TF-IDF. Similar results were found for several TF-IDF combined with machine learning, with a slightly better performance than individual classifiers. Overall, if one had to choose only one set of features, the best option is an hybrid ensemble (TF-IDF with expert rule-based annotator), which outperforms on average the model combinations with an average kappa of 0.77 (from the classifiers giving the best performance on each dimension, *i.e.* NB on dimensions 1 and 2, GBT on dimension 3 and K-NN on dimension 4).

When considering the combinations involving ML-based classifiers, the ML-based annotator combined with expert rule-based outperforms slightly the base-level machine learning on dimensions 1, 3 and 4 compared to the other ML combinations. Similarly to TF-IDF, the hybrid ensemble (ML with expert rule-based annotator) gives an average kappa of 0.77 instead of 0.74 for the base-level ML.

The combination of the three types of approaches obtains a performance similar or lower than the two other previously mentioned hybrid ensembles.

7. CONCLUSION

In this paper, we have shown that even with a small training set (less than 1000 questions), it can be useful to add ML-based approaches to complement a manually crafted annotator using a stacking approach to combine classifiers with each other. Using an hybrid ensemble of machine learning-based (or TF-IDF-based) annotators with a previously existing annotator seems to be the best approach, leveraging

the benefits of each approach. Combining TF-IDF and ML-approaches, however, does not seem as relevant. In our case, the hybrid ensemble models helped in increasing the performance for almost all dimensions, thus replying positively to our two initial research questions. It is worth noting though that the use of WordNet to reduce the vocabulary did not help in increasing the classifiers performance in our case.

One of the limits of this paper is that we considered only a single coding scheme and dataset. The increase in kappas can also be sometimes seen as modest, but this is to be put in perspective with the fact that human coders using this coding scheme rarely can reach a kappa superior to 0.75 on such a task. Moreover, one should note that the dimensions that were improved were the ones that were the furthest from the human coder performance. To conclude, we believe our result can open the perspective to easily improve the performance of various speech act and message annotators which often only rely on expert rules annotators.

ABSTRACT

With the advent of new data collection techniques, there has been a growing interest in studying co-located groups of students using Multimodal Learning Analytics [3] to automatically identify collaborative learning states. In this paper, we analyze a multimodal dataset (N=84) made of eye-tracking, physiological and motion sensing data. We leverage unsupervised machine learning algorithms to find (un)productive collaborative states. We found a three-states solution where different states (and transitions between them) were significantly correlated with task performance, collaboration quality and learning gains. We interpret these findings in light of collaborative learning theories and discuss their implications for studying groups of students using MMLA.

Keywords

Multimodal Learning Analytics; Eye-tracking; Physiological Sensing; Motion Sensing; Unsupervised Machine Learning.

1. INTRODUCTION

The last decade has seen educational researchers go beyond the study of conceptual learning to understand non-cognitive skills. These skills are considered central for preparing students for the challenges of the 21st century and turning them into resilient, creative, curious and collaborative individuals. Additionally, new learning environments are becoming popular to foster those skills, such as makerspace and digital fabrication labs. While there has been some important progress made in the study of 21st century skills, measuring and assessing them remains a challenge. Most educational researchers and practitioners still rely on traditional collection tools such as participant observations and in-depth interviewing. While research strategies provide valuable insight into learning and development, they are no longer the most efficient way of collecting data.

With the advent of new data collection techniques, however, there has been a growing interest in capturing 21st century skills using Multimodal Learning Analytics (MMLA; [3]). MMLA is about using high frequency sensors, such as eye-trackers, motion sensors, physiological devices and brain sensors to capture students' learning trajectories. Additionally, by combining multiple sensors

it is possible to study collaborative learning groups and capture various aspects of productive collaborations. Traditionally, these sensors have been studied in isolation. The promise of MMLA is to combine multimodal data sources to capture a more holistic picture of students' learning. Being able to capture 21st century skills [6] (such as collaboration) in real time opens new opportunities for providing feedback and designing new kinds of interventions to teach these skills.

The paper is organized as follows. First, we review the literature on several constructs related to collaborative skills that can be captured using high frequency sensors (e.g., Joint Visual Attention, Physiological Synchrony, body postures). We then describe the study that generated our dataset and detail how these constructs were measured. Finally, we present findings where we identified collaborative states using unsupervised machine learning algorithms and discuss their implications.

2. Literature Review

For decades, socio-constructivist theories have emphasized the importance of social interactions for learning (e.g., [12]). Among other things, collaborative learning can help students develop critical thinking skills, increase their motivation, provide a support system and facilitate assessment by making learning visible [10]. Capturing collaborative processes, however, remains a challenge – even though researchers have argued for almost a century that we need more rigorous ways to capture learning processes [23]. In the study of collaborative learning, Dillenbourg [8] argues that “empirical studies have started to focus less on establishing parameters for effective collaboration and more on trying to understand the role which such variables play in mediating interaction. This shift to a more process-oriented account requires new tools for analyzing and modelling interactions”. Below we review how Multimodal Learning Analytics (MMLA; [3]) can help us make a first step in this direction. More specifically, we describe how dual eye-tracking, motion sensors and physiological sensors can provide fine-grained indicators of collaboration.

2.1 Joint Visual Attention and Dual Eye-tracking

Joint Visual Attention (JVA; [4]) is the most fundamental building block by which human beings coordinate their actions, establish a common ground, advance toward a common goal, solve problems, and learn together. It is a construct that encompasses numerous visual processes, and is observed as important for learning to socialize [4], engaging collaboratively [22], and developing social motivation [16] for diverse populations in varying collaborative conditions. The last decade has seen a small but growing number of researchers take advantage of synchronized eye-trackers to quantitatively measure gaze alignment in various collaborative

Karina Huang, Tonya Bryant and Bertrand Schneider "Identifying Collaborative Learning States Using Unsupervised Machine Learning on Eye-Tracking, Physiological and Motion Sensor Data" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 318 - 323

situations interpersonal communication [14]. With the emergence of MMLA, quantifying gaze synchronization in remote learning and problem-solving environments has similarly popularized. In video lectures, projecting the professor's gaze onto the screen (as a substitute for the use of deictic gestures in co-located teaching environments) while making explicit references to information on slides can be useful for students and increase learning gains [20]. In co-located collaborative problem-solving situations, students' level of JVA has been found to be positively correlated to behaviors such as managing group dialogue, reaching consensus, and equally dividing work between members of the group [18]. Regardless of the context, JVA measurement and visualization tools are providing new ways to allow for objective inferences to be drawn about gaze synchronization as it relates to various collaborative states.

2.2. Body Postures and Motion Sensing

Students' use of their bodies has received a great deal of attention from learning scientists over the last decades. Numerous studies have unraveled links between students' understanding of various topics [1, 5] and specific gestures [15]. More generally, there has been a plethora of studies linking people's intuitive representations of everyday situations and bodily language (e.g., embodied cognition [2]). Recently, researchers have started using motion sensors to provide more fine-grained analyses of body postures in collaborative learning settings. For example, [19] found that hand movement could distinguish between students who were more dominant (called "drivers") and those who were more passive (called "passengers").

2.3 Physiological Sensors and Group Synchrony

Researchers have recently started to use EDA sensors (Electrodermal Activity) to look at collaborative learning interactions. [13] describes four measures of physiological synchrony in small groups of students: Signal Matching (SM), Instantaneous Derivative Matching (IDM), Directional Agreement (DA), and Pearson's correlation coefficient (PC). They found that IDM was related to collaboration quality and task performance, and DA with learning gains. In a separate publication, we applied the same methodology to the dataset described in this paper and found that those indices provided significant predictors for collaborative learning [7]. DA was significantly correlated with collaboration quality, IDM with task performance, and PC with learning gains. In a different study, [9] found that DA was the best predictor for task performance. It is interesting to note the discrepancy between the findings above, which is likely due to the nature of the task and the way we operationalized our constructs. But overall, researchers have found that physiological synchrony seems to be sensitive to social interactions in a variety of contexts.

In summary, there is significant evidence that collaborative learning processes can be captured using multimodal sensors. This paper goes one step further by combining modalities together, instead of studying them in isolation.

3. METHODS

3.1. The Study

The dataset used in this paper was collected as a part of a Multi-Modal Learning Analytics study [21]. 84 participants (Male = 40%; Female = 60%) with no prior programming experiences were randomly assigned to dyads ($N_{\text{dyad}} = 42$) and programmed a robot to solve a series of mazes during 30-minute sessions (Fig. 1). Each dyad was randomly assigned to one, both, or neither of two

designed interventions: 1) a verbal explanation of the benefits of collaboration (e.g. past research findings using equity of speech time as indication of collaboration quality), and 2) real-time visualizations showing relative verbal contributions of each participant. The number of dyads was evenly distributed among four experimental conditions. For the analyses reported below, we analyze the aggregated data and did not consider the four experimental conditions.

During each session, we used two Empatica E4 wrist sensors to track participants' physiological activities, two Tobii Pro Glasses 2 eye-trackers to capture eye gaze, and one Kinect sensor to record movement as well as facial expressions. Participants were given a survey before and after the study for assessment of their computational thinking and collaboration experiences. A dyad's collaboration, task performance, and learning outcomes were assessed by the researcher responsible for running the session; ratings were given on nine scales based on prior work by Meier, Spada, and Rummel [11] (inter-rater reliability of 0.65 – i.e., 75% agreement). Analyses of learning gains, coding schemes, inter-judge reliability scores and individual sensor data have been reported in [21]. The current analysis aimed to combine all sensor data in order to identify collaborative states.

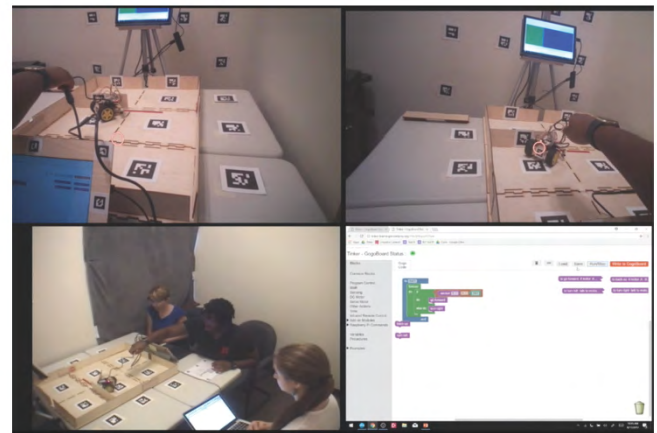

Figure 1. Two participants from the study. The top images show the video feed from the mobile eye-trackers (with a participant's gaze shown on the top right image). The bottom left image shows a 3rd person perspective. The bottom right image shows the programming environment.

3.2. Data Collection

3.2.1. Empatica

The Empatica E4 wristbands collected participants' accelerometer, blood volume pulse (BVP), interbeat intervals (IBI), electrodermal activities (EDA), and heart variability (HR). The current study focused on the EDA data, which is a measure of skin potential, resistance, conductance, admittance and impedance. Participants were asked to tag the wristbands before and after each step during the sessions (i.e. before and after completing the maze task). We synchronized the dyadic data according to the tags and timestamps of the sessions. The resulting data frame per dyad contained timestamp, four aggregated measures of physiological synchrony described in the Measures section below, and EDA values of each participant. Five dyads were removed from the current analysis because the sensor data was missing, too noisy, or identified as outliers (see [21]).

3.2.2. Tobii Pro Glasses 2

The Tobii eye-trackers generated data at 50Hz per second and recorded the x and y coordinates of each participant's eye-gaze relative to its point of view. The resulting data frame per dyad contained time indicated by second (ranging from roughly 1s to 1800s), the x and y coordinates of each participant's eye gaze and counts of joint visual attention (JVA) by pixel distance. The eye-tracking data was synchronized with the EDA data by briefly presenting a fiducial marker on the computer screen between each step of the session; participants were asked to tag this event on their wristband as accurately as possible. While we were able to clean and synchronize most dyadic data by seconds, two groups were excluded from the current study due to missing data.

3.2.3. Kinect

The Kinect motion sensor captured around 100 variables related to a participant's body joints and skeleton. The sensor generated data at 30 Hz per second, resulting in about 3,000 observations per second per participant. Noisy data (e.g. when the session facilitator entered the Kinect frame) were removed for each group, after which data were aggregated by second according to timestamps generated by the Kinect sensor. Researchers manually trimmed the Kinect data for each 30-minute session based on video records and aligned them with the eye-tracking and EDA data. Nine dyads were removed from the current study due to missing data.

3.2.4. Synchronizing All Data

The Empatica and Kinect data were synchronized by trimming each session to exactly 30 minutes and outer-joining sessions' data on the timestamp column. Per-dyad eye-tracking data were synchronized by matching the "second" column (i.e. from 1s to 1800s during a 30-minute session; see Fig. 2) generated based on timestamps of the EDA data. For analysis purpose, we concatenated all per-dyad data into a master data frame, with an additional column indicating to which session the data belonged to. Due to an unequal amount of data loss between sensors, two datasets were created for analysis: 1) Combined EDA and JVA ($N_{\text{dyad}} = 35$), and 2) Combined EDA, JVA and Kinect ($N_{\text{dyad}} = 31$). The current analysis used the second dataset, including 67,656 rows and 19 columns of by-second original and scaled data from all sessions investigated (Fig. 2).

session	second		DA	PC	IDM	SM	jva100	moveDiff	headDiff	shoulderDiff
0	2	1	0.233333	-0.447563	0.177397	0.208709	24.0	1.941329	0.047057	0.658437
1	2	2	0.232708	-0.445837	0.177548	0.207804	7.0	2.013969	0.040868	0.654975
2	2	3	0.233125	-0.442000	0.177468	0.206289	18.0	1.825878	0.048828	0.642805
3	2	4	0.234583	-0.439776	0.176532	0.205172	23.0	1.675585	0.037022	0.648898
4	2	5	0.234375	-0.438995	0.175948	0.204015	6.0	1.967405	0.042931	0.646596

Figure 2. A snapshot of the final data frame. Note that the scaled column measures are excluded for legible visualization.

3.3. Data Processing

3.3.1. Electrodermal Activities (EDA)

Four measures of physiological synchrony were computed based on participants' electrodermal activities (refer to [7] for an exhaustive description of these measures and related analyses): 1) Pearson's Correlation (PC) represented the linear relationship between the EDA level of each participant in a dyad; a strong, positive correlation indicated that the dyad was physiologically activated at similar times. 2) Directional Agreement (DA) captured whether the EDA level of each participant in a dyad increased or decreased at the same time steps; an increase in DA value in the positive direction indicated higher physiological synchrony. 3) Signal Matching (SM) was computed as the area between data curves of each dyad. A greater SM value indicated lower

physiological synchrony. 4) Instantaneous Derivative Matching (IDM) computes, for each dyad, the level of signal matching between slopes of participants' signal curves. A higher IDM value indicated lower physiological synchrony between participants.

3.3.2. Joint Visual Attention (JVA)

JVA was qualified by looking at participants' location of eye gaze after mapping these coordinates into a common plane (Fig. 3; see [17] for the complete procedure of computing JVA). The current analysis looked at the number of JVA per second where a dyad's eye gazes were within 100 pixels of each other.

Figure 3. The procedure used to compute Joint Visual Attention (the left side shows the data from the mobile eye-trackers, and the right side shows how the participants' gaze were mapped onto a common plane using a homography).

3.3.3. Kinect

We explored various collaborative measures based on prior work [18, 23]. The current analysis aggregated three measures of movement differences per dyad: 1) Total difference in movement (MoveDiff), 2) Vertical difference in head orientation (HeadDiff), and 3) Horizontal difference in shoulder orientation (ShoulderDiff). Total movement was computed by taking the Euclidean distance of all joint coordinates; difference in movement within dyad was the absolute difference in the participants' total movements. Vertical difference in head orientation was the absolute difference in the y coordinates of participants' heads. Horizontal difference in shoulder orientation was calculated by taking the absolute value of the difference between 1) the absolute difference in x coordinate of the left shoulder of the left participant and the x coordinate of the right shoulder of the right participant, and 2) the absolute difference in the x coordinate of the right shoulder of the left participant and the x coordinate of the left shoulder of the right participant.

3.3.4. Outcomes Measures

The study generated three types of outcome measures: collaboration quality [11] (sustaining mutual understanding, dialogue management, information pooling, reaching consensus, task division, time management, technical coordination, reciprocal interaction, individual task orientation, and Collaboration – the sum of those scores), overall task performance (task performance, task understanding, improvement over time) and learning gains. Collaboration and Task performance of each dyad was hand-coded by the experimenter at the end of the session. The dyad's learning gain was assessed through a pre-test and post-test. For more information, please refer to [21].

3.4. Analysis Strategy

We used K-Means Clustering with Euclidean distance to identify different collaborative states. In particular we attempted clustering using all sensor data simultaneously. All data were transformed into

z-scores before clustering; the scaled values reported in results refer to the z-scores. Note that the clustering assignment was performed on the aggregated data with per-second data from all dyads. The collaborative states were identified regardless of group and time. We used the elbow curve to identify the optimal number of clusters for each clustering strategy; the current analysis used within-cluster sum of squared as the indication of distortion. We proceeded our analysis using $K = 3$.

Upon assigning per-second data to clusters, we computed 1) time spent in each cluster, and 2) transition probabilities between clusters for each session. Correlations between time in cluster, transition probabilities, and each qualitative outcome measure were then investigated and visualized. The results section below summarizes our findings by outcome measures.

4. RESULTS

4.1. Correlation Check

To check for underlying relationships between our sensor data aggregated at the second level and the qualitative outcomes, we first checked for correlations between each sensor and qualitative measure. Significant correlations were observed between SM and Learning ($r = -0.4$, $p = 0.025$), and between JVA and sustaining mutual understanding ($r = 0.41$, $p = 0.027$). In accordance with previous analysis [7], no other significant correlation was observed.

4.2. Cluster Centroids

Centroid 1 values were the highest in all movement variables, suggesting cluster 1 as a state where dyads exhibited the most total movement difference, vertical difference in head orientation (e.g. a person standing up versus the other seated), and horizontal difference in shoulder orientation (when dyads were far apart from each other). Centroid 2 values were the highest in DA, PC, JVA, and the lowest in IDM, and SM; cluster 2 indicated a state where dyads were physiologically synchronized and actively sharing eye gaze. In contrast, cluster 3 appeared to be a state where dyads were the most desynchronized. Centroid 3 had the highest SM, IDM, and the lowest DA, PC values. Table 1 provides a summary of the 3 clusters identified by K-means Clustering, we will use the identified states to address the clusters in the following sections.

Cluster	Physiological Synchrony	Joint Visual Attention	Movement Difference	State
1	Average	Average	Highest	Neutral
2	Highest	Highest	Low	Collaborative
3	Lowest	Lowest	Low	Non-Collaborative

Table 1. Summary of clusters by sensor data.

4.3. Collaboration

Figure 5 represents the scaled and unscaled sensor data values by cluster centroid. The overall collaboration measure ($r = 0.50$, $p = 0.009$) was significantly correlated with time spent in the collaborative state. Time spent in the collaborative state was significantly correlated with sustaining mutual understanding ($r = 0.42$, $p = 0.031$), dialogue management ($r = 0.51$, $p = 0.008$), reaching consensus ($r = 0.48$, $p = 0.013$), task division ($r = 0.49$, $p = 0.012$), and reciprocal interaction ($r = 0.47$, $p = 0.015$). By interpretation of the EDA measure, dyads were highly, physiologically synchronized in the collaborative state. In contrast, dyads were highly desynchronized in the non-collaborative state,

as the state corresponds to the lowest DA, PC and highest SM, IDM values by clustering. Time spent in the non-collaborative state was significantly, negatively correlated with dialogue management ($r = -0.49$, $p = 0.008$), task division ($r = -0.45$, $p = 0.015$) and collaboration ($r = -0.42$, $p = 0.030$).

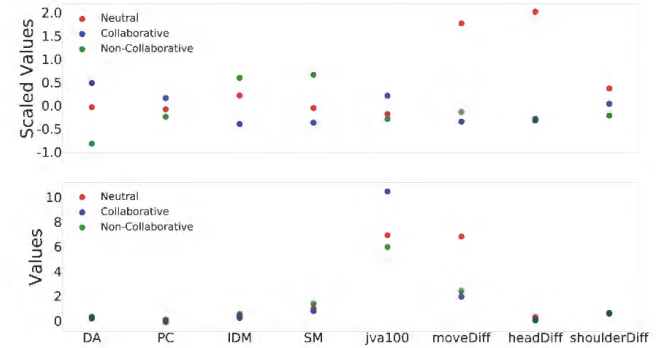

Figure 4. Sensor data mean values by cluster.

Correlations between state transition probabilities and qualitative outcomes rendered the same interpretation: the higher the probability that a dyad would transition into a desynchronized, or non-collaborative state, the lower the rating in collaboration ($r = -0.41$, $p = 0.027$).

Figure 5. Correlations (left) and p-values (right) between time spent in cluster and qualitative outcome variables (* $p < 0.05$).

4.4. Task Performance

As shown in Fig. 6, time spent in the non-collaborative state was significantly correlated with improvement over time ($r = -0.47$, $p = 0.018$). The more likely a dyad were to transition into the desynchronized state, the lower the rating for task understanding ($r = -0.47$, $p = 0.01$, See Figure 6), and improvement over time ($r = -0.53$, $p = 0.005$). Furthermore, there was a marginally significant correlation between the probability of remaining in the neutral state and code quality ($r = -0.37$, $p = 0.042$); the more a dyad was different in movement, the lower the code quality as evaluated by the session facilitator.

Figure 6. Correlations (top) and p-values (down) between transition probabilities and qualitative outcome variables (* $p < 0.05$, ** $p < 0.01$).

4.5. Learning Gain

We did not observe any significant correlations between learning and time spent in any of the collaborative state identified. However, learning was significantly and negatively correlated with the probability of remaining in the non-collaborative state ($r = -0.47, p = 0.008$). The more likely a dyad were to stay desynchronized, the lower the rating in learning gain.

5. DISCUSSION

Overall, our results suggest that K-Means Clustering is an effective method for identifying collaborative states. In accordance with previous findings, higher JVA in the current analysis significantly correlated with higher ratings of collaboration, more specifically in sustaining mutual understanding. This implies that sharing gaze facilitates collaboration by making aware the object, or the intent, of communication. In comparison with previous correlation findings [7], we were able to draw connections between the EDA measures and collaborative outcomes using clustering analysis. Specifically, physiological synchrony within dyads correlated with higher ratings in quality of collaboration, including sustaining mutual understanding, dialogue management, reaching consensus, and task division. This indicates, intuitively, that when participants in a dyad were in sync with each other, they were more likely to agree, understand, and coordinate in task with each other. Moreover, the larger the difference in movement and position within a dyad, the lower the code quality. One interpretation could be that the longer a dyad spent apart from each other, the less collaborative they were, or were deemed to be, and therefore, the lower the resulting code quality.

In a case study that compared the most collaborative (Group 11) and most non-collaborative (Group 5) groups, we observed that desirable collaborative qualities support the narrative, and the disaggregated graphs (Fig. 7) we created to depict them, that collaborative states are closely associated with levels of JVA and DA value.

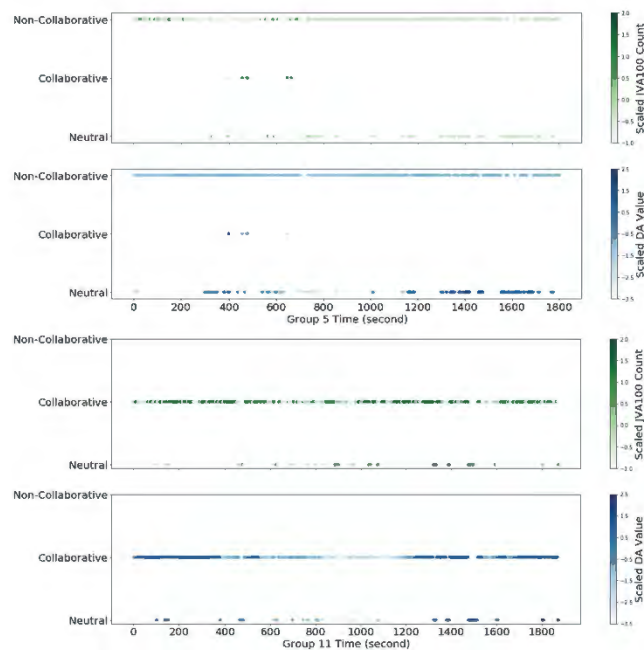

Figure 7. Progression of collaborative states by DA and JVA value in group 5 and group 11.

Though Groups 11 and 5 displayed collaborative (Group 11) and non-collaborative (Group 5) qualities rather consistently across the activity, each group mirrored qualities of the other. For example, while thinking aloud was a consistent quality exhibited by Group 11 across the activity, the participant on the left almost always remained in an observational role, which could have led to low learning gains. However, Group 11 achieved the highest learning gains of all groups in the study. One reason for this outcome could be the intent of the observer. High learning gains and consistent observation seemed to be a mode of learning for the participant on the left. This explanation supports an interpretation of observation not as a culprit of poor collaboration, but an assistant to learning, given a particular learning context. On the other hand, Group 5 also showed behaviors that were contrary to main themes that arose from their interactions. Take for instance their dialog that occurred in the middle of the activity. There, they exhibited seemingly desirable qualities in collaborative learning such as asking for help, asking clarifying questions, using demonstrative actions such as re-running code to convey conception of problem, and a continuous interactive dialog; however, demonstration of these qualities was more of an abnormality than a change in behavior. Furthermore, each participant steadfastly performed their roles. One interpretation of why this temporary change in mode of operation did not stick goes back to the very definition of collaboration: a result of continuous attempts to construct and maintain a shared problem space. This means that establishing a collaborative state two thirds of the way through the activity is perhaps too difficult of a cognitive shift when working modes have been established.

Main Results	Interpretation	Implication
Time spent in cluster 2 is sig. correlated with collaboration quality	Productive collaboration is characterized by increased levels of JVA and physiological synchrony	combining JVA values with PCIs provide better predictors for collaboration quality than just individual JVA or PCI
Staying in cluster 1 or 3 is neg. correlated with learning	The more participants stay in a state where they are not looking at the same place and are physiologically desynchronized prevents them from learning	we could potentially detect when people are in this state in real-time and offer suggestions for getting participants back on track.
Time spent in cluster 3 is neg. correlated with task performance	Non-collaborative states are associated with less task understanding and improvement over time.	*we didn't observe a positive significance with cluster 1, perhaps that while being highly synchronized and actively sharing eye gaze doesn't necessarily leads to more task understanding / improvement overtime; there's a reverse effect when participants were not at all collaborative by EDA/JVA measures.
Staying in cluster 1 is neg. correlated with code quality	The more time participants spent apart from one another, the lower the code quality.	Spending time apart from one another may indicate individual exploration, which in learning settings, may imply that participants were in need of guidance in order to proceed with task.

Table 2. Summary of results.

Finally, we found learning gains to be significantly associated with EDA measures. Particularly, the more likely a dyad were to remain desynchronized physiologically, the less likely that they had learned, or were evaluated to have learned from the task. Overall, we found that combining multimodal measures of collaboration together (e.g., eye-tracking, physiological, motion data) provides us with richer results: we found more (and stronger) significant correlations with our dependent measures. Table 2 summarizes the main results of this paper.

Nonetheless, it is important to note the limitations of the current analysis. For one, the aggregated Kinect measures utilized in the

current analysis might not have best captured motor differences between collaborative and non-collaborative dyads. The current analysis only examined dyad's motor differences on single dimensions, future work should aggregate movement measures based on multiple dimensions (e.g. movement angle) in order to better capture (non-)collaboration in motion. As we identified the number of collaborative states ($K = 3$) using distortions computed with the current dataset, it is possible that this number is not definitive and is unique to the current study. We concluded from exploratory analysis that the implications differed as we increased the number of clusters, and/or reduced our variable dimensions. Moving forward, it is of our interest to find the optimal combination of measures, and the optimal number of states that best characterize the (un)productive collaboration.

5. CONCLUSION

The current study used unsupervised machine learning algorithms to effectively identify different states of collaboration. Combining eye-tracking and physiological-activity data better predicted collaboration quality than the two types of sensor data apart. The longer two partners were not sharing gaze, and were desynchronized from one another, the worse their task performance and the less they learned. Identification of collaborative states and their characteristics through sensor data potentially allows us to monitor collaboration in real-time, detect ineffective cooperation, and keep partnership intact. Future work should explore movement measures of various dimensions to best capture participants' postures and motions.

In summary, this paper contributes to the application of MMLA in open-ended learning environments for capturing 21st century skills. We argue that multimodal sensors can capture different aspect of productive collaboration, and that combining them can provide us with a more complete picture of productive social interactions. Because we tend to "teach what we can measure", developing tools that can capture 21st century skills is a crucial step toward studying and fostering them. This paper makes a first step in this direction by leveraging multimodal sensor data.

ABSTRACT

Recent work in predictive modeling has called for increased scrutiny of how models generalize between different populations within the training data. Using interaction data from 69,174 students who used an online mathematics platform over an entire school year, we trained a sensor-free affect detection model and studied its generalizability to clusters of students based on typical platform use and demographic features. We show that models trained on one group perform similarly well when tested on the other groups, although there was a small advantage obtained by training individual subpopulation models compared to a general (all-population) model. Lastly, we perform a series of simulations to show how generalizability is affected by sample size. These results agree with our initial analysis that individual subpopulation models yield a small advantage over all-population models. Additionally, we show that training sizes smaller than 1,500 yield unstable models which make generalizability difficult to interpret. We discuss applications of this work in the context of developing large-scale affect detection models for diverse populations.

Keywords

Affect Detection, Clustering, Generalizability, Sensor-free, Online Learning

1. INTRODUCTION

Computer-enabled classrooms and online learning environments are becoming increasingly common methods of learning [12, 25]. Compared to traditional classroom settings, students must be more self-regulated when interacting with online platforms [15]. In [20], Pekrun discusses how emotion and its regulation are key factors in educational achievement. It is then important to consider student affect when developing intelligent tutors and educational platforms. A review of affect-sensitive instructional strategies, particularly for intelligent tutors [5], discusses how affect- and motivation-sensitive strategies can promote student engagement. However, the authors found that a “one-size-fits-all approach, where variants of the same strategy are indiscriminately used for all learners and in all situations” limits the overall effectiveness of these tutors in targeting individual student needs. This observation motivates a more detailed analysis of how affect detectors trained on a general population generalize across different subpopulations.

In this work, we extend previous research exploring the generalizability of sensor-free affect detectors. We trained models

predicting positive and negative affective states using interaction data from an online algebra learning platform along with self-reported affect. A novel component of our work compared to previous work (e.g., [2]) is the scope of our dataset, which encompasses 69,714 students across a nine-month period. We extend the previous work in [9]. This enables a more detailed exploration of generalizability than was previously achievable.

1.1 Related Work

Reviews of issues and methods of sensor-free affect detection are covered in other work, which we summarize here. Baker and Ocuppaugh review work in sensor-free affect detection in educational software and discuss methods for collecting ground-truth labels [3]. Specific to this work, they note that student-generated responses are likely more accurate than labels from external coders. Second, [9] reviews a representative collection of sensor-free affect detection models developed in authentic classroom environments. The authors conclude that the studies show the potential success for sensor-free affect detection models in authentic environments but are limited by small sample sizes (20-646 students) from mostly homogenous samples, which limits claims or tests of generalizability.

Recent work in machine learning and prediction calls for increased awareness of how models perform for individual subpopulations in addition to overall accuracy. In [10], Kusner et al. introduce counterfactual fairness, where models should be unaware of protected attributes such as gender and race. Fair models should generalize by generating similar predictions for individuals with similar features, regardless of their protected attributes. In [26], Sculley et al. suggest slicing analysis as a method to evaluate fairness, where predictive model performance is evaluated by “slicing” along subpopulations or protected attributes. This is an alternative to measuring overall model accuracy, which can ignore disadvantaged subpopulations. In response, Gardner et al. present a framework for using slicing analysis in predictive modeling [7].

Related to this discussion on generalizability, several studies have measured how models generalize across cultural contexts. Ogan et al. [18] found differences in collaboration, engagement, and student needs between cultural groups. In [24], San Pedro et al. trained models detecting student carelessness in Philippines. They showed generalizability by testing these models on previously collected data from students in the USA. In [27], Soriano et al. compared models of help-seeking behavior. By training models on each group and testing on the other groups, they showed that models for Philippines and USA generalize to each other but not to Costa Rica.

Besides cross-country generalization, several studies investigated how predictive models generalize over demographic attributes. In [17], Ocuppaugh et al. trained affect detection models on rural, suburban, and urban students. By training models on each group and testing on the other groups, they found that models for urban and suburban students generalized to each other but not to rural students. In [23], Samei et al. trained models of teacher question

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 324 - 329

asking behavior using data from urban and non-urban classrooms. They showed generalizability using the methods from [17].

Other studies measured the generalizability of predictive models over time. In [1], Baker et al. trained models detecting gaming the system behavior in a cognitive tutor. They showed generalizability by training models on data from three sessions and testing on the remaining session. In [4], Bosch et al. trained face-based affect detection models. They showed generalizability by training models on data from one day and testing on the other day.

Finally, some studies measured generalizability between different tasks or subjects. In [28], Stewart et al. compared models of mind wandering trained on students reading a scientific text or watching a narrative film. They found models trained on the narrative film dataset generalized to the scientific text dataset, but models trained on the scientific text dataset only generalized to the narrative film dataset after adjusting the predicted mind wandering rate. In [9], Hutt et al. found that models trained on data from students enrolled in Algebra 1 generalized to students enrolled in Geometry using “generic activity features” specifically designed for generalization.

1.2 Contribution of Current Study

This work contributes to the field of generalizability in sensor-free affect detection in three important ways. First, we extend beyond previous work by using data from a large, heterogeneous sample of students. Besides the noted studies that compare country-wide cultural differences, previous work relies on homogeneous samples such as individual schools, which yield sample sizes of hundreds of students. As discussed in [2], these sample sizes do not allow researchers to draw conclusions about the studied categories as a whole, so generalizability can only be tested in a minimal sense. In this study, we collected affect data from 69,174 students at 1,898 schools in the state of Florida. Because Florida closely represents the demographic composition of the United States in terms of race and ethnicity [29, 30], this allows us to study the generalizability of our models to other students in the country.

Second, we measure the generalizability of our models in terms of usage characteristics over an entire school year. In previous studies, data are collected during one or a few sessions, which overlooks long-term student behavior. This work uses interaction logs from an entire school year and measures student use over several sessions. We use clustering analysis to identify common usage patterns and show that our models generalize across these clusters.

Lastly, we provide simulation experiments to inform the number of instances needed in order to construct generalizable models. Specifically, we estimate the advantage obtained by training models on individual groups across different sample sizes.

2. DATA

We used a previously published dataset [9] but all analyses reported here are new.

2.1 Algebra Nation

Data was collected through Algebra Nation, an online math learning platform developed by Study Edge. Algebra Nation supports over 150,000 students studying Algebra 1, Algebra 2, and Geometry each semester. Students can use Algebra Nation in a variety of contexts; some teachers integrate the platform into their regular classroom time while some students only use it to study or help with homework. Students can access Algebra Nation using a mobile app or on the internet (<https://www.algebranation.com/>). For this study, we used data from students enrolled in Algebra 1.

In Algebra Nation, course material is organized according to state mathematics standards. Although the topics are ordered according

to the curriculum, students are free to skip topics as necessary or learn the material in a different order.

For each topic, students can watch a video lecture from one of several tutors. In addition to watching videos, students can use the *Test Yourself* quiz feature for each topic, which randomly selects 10 questions aligned with state standards. After attempting a quiz, students can review feedback on their answers or watch solution videos. Lastly, students can get more help through the *Discussion Wall* where they can interact with other students and study experts hired by Algebra Nation. Students can earn *karma points* by answering questions posted by other students. However, students primarily spend time watching videos and taking quizzes rather than engaging in the social functions of the platform.

2.2 Affect Surveys

Due to the large number of students in the study and because students can use the platform in multiple contexts, we collected ground-truth affect labels using a self-report survey rather than through expert coders or human observers (see [16, 22]). These surveys were pseudo-randomly triggered based on student activity on the platform. Specifically, we manually assigned probabilities to each action so that triggered surveys were not overly intrusive and there was an adequate sampling of infrequent actions (e.g., wall posts) compared to highly frequent ones (e.g., seeking in videos).

The survey was displayed in a pop-up window. Students had the option to ignore surveys. To decrease the prevalence of the surveys, once a survey was triggered for a student, the student was removed from the survey pool for two weeks. Our dataset includes surveys from the 2017-2018 school year (September through May). In this time, 69,174 students responded to at least one survey. The mean number of survey responses per student was 1.94 (median = 1). Of the students that responded, the minimum number of responses was 1 and the maximum number of responses by any student was 14.

Each survey targeted one affective state, randomly selected, from the following: Anxiety, Boredom, Confusion, Contentment, Curiosity, Disappointment, Engagement, Frustration, Happiness, Hopefulness, Interest, Pride, Relief, Sadness, Surprise, Mind Wandering, Pleasantness, and Wakefulness. We chose several states because they closely relate to learning [21] while others address core dimensions of affect such as valence and arousal [11]. Mind Wandering, Pleasantness, and Wakefulness represent bipolar concepts, so we used a seven-point scale with contrasting options and presented prompts for each polarity (e.g., sleepy/awake). The other states used a five-point scale ranging from “Not at all ___” to “Very ___”. In our analysis, we linearly scaled all survey responses to lie in a five-point range so that all states are represented equally.

2.3 Generic Activity Features

We recorded student activity on Algebra Nation using 22 features that did not depend on specific content (e.g. which video was watched or a particular quiz question). These activity features included attempting quizzes, watching videos, and interacting with the wall or discussion board. Based on our prior work [9], we counted the number of occurrences of each feature over 30-second chunks and summed the counts for each action across 5-minute window lengths preceding an affect survey. In some cases, the platform measured an unnaturally high amount of activity (e.g. playing/pausing a video 100 times within 30 seconds). We addressed these outliers by limiting each 30-second chunk to 10 recorded activities.

2.4 Usage Features

In addition to session-specific generic activity features, which were used to train the models, we were interested in investigating

generalizability to differences in how students interact with the platform over an entire school year. To do this, we defined five usage features. First, we calculated the proportion of sessions students use their mobile device compared to a desktop computer as this may indicate the context in which students are using the platform (e.g., at home or while commuting). Second, we calculated the proportion of sessions in the spring semester compared to the fall semester. We were interested in this feature because students must pass the algebra standardized exam that is offered in the spring semester in order to graduate from high school. To model how much students use the platform, we calculated the number of sessions and the average length of each session. Students may leave an active session open for long session times in their browser while switching to another task or repeatedly log into the platform without recording any meaningful interactions. We replaced these outliers with the 99th percentile value for the average length and number of logins. Finally, we calculated the mean time of day that students use the platform, which can indicate whether students primarily use the platform during the school day or at home. Usage data was available for 235,756 individual students, including those who did not receive or respond to any surveys.

2.5 Demographics

We also obtained records of demographic data of 118,177 students from the Florida Department of Education. This dataset includes students from grade 6 through grade 12, from which we defined three groups. We defined the first group as Middle School (54%), which includes grades 6 through 8. These students are often advanced and are enrolled in the Algebra course earlier than is typically expected by state standards [6]. The second group is Grade 9 (37%). We chose to keep this grade separate because it has one of the largest enrollment numbers and grade 9 is when students are enrolled in the course during the typical mathematics sequence. Lastly, we defined High School (9%) as grades 10 through 12. These students are often behind in the typical mathematics sequence and struggle to pass the course before they graduate. For gender, the available data classifies students as Male (49%) or Female (51%), which we took at face value.

This dataset records student eligibility for free or reduced-price (F/R) school lunch, which is one indicator of socioeconomic status (but see Harwell & LeBeau [8]). We defined the groups as F/R (53%) and Other (47%), with the latter reflecting those who did not qualify or did not apply. We combined free and reduced because there were so few students that qualified for a reduced-price lunch.

Finally, this dataset includes data on race and ethnicity. We defined these groups to approximately balance group size: White (72%), Black (23%), Hispanic (32%), and Other (13%; Asian, Native American, Pacific Islander, and Mixed).

3. CLUSTERING

We clustered participants based on usage characteristics and demographics to investigate the generalizability of the affect models across clusters. To determine the number of clusters, we inspected the dendrogram generated with Ward hierarchical clustering [31] using the SciPy library (<http://www.scipy.org/>). For efficient clustering, we randomly sampled 1,000 instances. We then used the k-means algorithm [14] to construct the clusters using scikit-learn [19]. We chose to use all available students regardless of their participation in the surveys since our goal was to generalize over as many students as possible.

We constructed usage clusters using the five features described in Section 2.4. We first scaled each of these features to [0, 1]. The above procedure yielded five clusters (Table 1). One group (U1) showed heavy usage patterns (signified by long sessions and numerous log-ins). Two groups were defined by primarily mobile sessions and were further differentiated by sessions focused in either the fall (U4) or spring (U5) semester. Finally, two groups showed particularly light usage patterns and were differentiated by sessions focused in either the fall (U3) or spring (U2) semester.

Next, we constructed clusters using the demographic features described in Section 2.5. We dummy encoded our variables resulting in seven features indicating grade level, three features indicating lunch status, seven features indicating race/ethnicity, and one feature indicating gender. The above procedures yielded seven clusters (Table 2). Grade level largely differentiated clusters. Only

Table 1. K-means cluster centers based on typical usage. Distinguishing features are bolded.

ID	Cluster Description	Session Time (min)	Num. Sessions	Prop. Spring Use	Prop. Desktop Use	Time of Day (hour)	Prop. of Users
U1	Spring semester, heavy use	45.46	25.44	0.75	0.90	14.19	0.20
U2	Spring semester, light use	14.26	3.53	0.96	0.99	14.86	0.35
U3	Fall semester, light use	13.81	3.46	0.11	0.99	14.81	0.28
U4	Fall semester, mobile use	21.38	9.54	0.19	0.30	13.25	0.07
U5	Spring semester, mobile use	29.66	10.95	0.93	0.27	13.21	0.10

Table 2. Demographic cluster centers. For clarity, only distinguishing features are displayed and are bolded.

ID	Cluster Description	Grade 7	Grade 8	Grade 9	Grade 10	F/R Lunch	White	Black	Asian	Prop. of Users
D1	Split grades, F/R lunch, Black	0.08	0.29	0.44	0.17	0.99	0.03	1.00	0.01	0.16
D2	Grade 7, not F/R lunch, White/Asian	1.00	0.00	0.00	0.00	0.20	0.80	0.06	0.16	0.10
D3	Grade 8, not F/R lunch, White	0.00	0.99	0.00	0.00	0.00	0.87	0.09	0.07	0.22
D4	Grade 8, F/R lunch, White	0.00	1.00	0.00	0.00	1.00	0.90	0.03	0.06	0.15
D5	Grade 9, F/R lunch, White	0.11	0.00	0.87	0.00	1.00	0.91	0.01	0.03	0.16
D6	Grade 9, not F/R lunch, White/Black	0.00	0.00	0.99	0.00	0.04	0.81	0.16	0.04	0.16
D7	Grade 10, split F/R lunch, White/Black	0.00	0.00	0.00	1.00	0.52	0.76	0.20	0.03	0.05

cluster D1 had a significant distribution of students across grade levels. Another differentiating feature was lunch status, where three clusters (D1, D4, D5) were largely comprised of students on F/R lunch. Four clusters were differentiated by race (D1, D2, D6, D7).

4. AFFECT DETECTION MODELS

4.1 Model-building Procedure

We used scikit-learn [19] to implement a supervised learning pipeline. We chose to use the Bayesian Ridge Regression algorithm [13] since it produced good overall results in previous work on the same data [9] compared to several more complicated alternatives.

We trained regression models using 10-fold student-level cross validation. For each fold, instances for each student were included in *either* the training or testing set. This practice reduces overfitting and increases the likelihood that the model will generalize to new students. In each fold, we trained a model using the generic activity features and generated predicted survey responses on the test data. We evaluated the performance of the model using the Spearman correlation as it assumes ordinal and continuous values. We then averaged these scores across folds to obtain a final accuracy score.

We trained prediction models for positive and negative affective valence rather than the original 18 states measured in the surveys. We initially trained a model for each state and calculated the correlation between the predicted survey responses for each state. These predictions were strongly correlated within positive and negative valence. We then trained positive and negative valence models using the combined set of states and generated predictions for the individual states. The mean performance of the valence models was similar to training individual affective models, so we chose to use the valence models for parsimony. For the positive valence models, we included the following states: Arousal, Contentment, Engagement, Happiness, Hopefulness, Interest, Pleasantness, Pride, and Relief. For the negative valence models, we included the following states: Anxiety, Boredom, Confusion, Disappointment, Frustration, Mind Wandering, and Sadness. We did not include Curiosity and Surprise since their valence does not clearly align on either direction.

4.2 Preliminary Models on Cluster Membership

We first investigated whether our models discriminated using group features rather than the generic activity features. To test this, we trained models using cluster membership as the training data instead of activity features. We expected these models to perform poorly since they are not simply reflecting group differences. Indeed, we found that the average Spearman correlations were low (between 0.02 and 0.05) for both cluster models.

4.3 Generalizability

Our main analysis focused on investigating how our models, trained on activity features, generalize across different clusters. First, we considered a general model trained on the entire dataset using 10-fold student-level cross validation. We then built cluster-specific models. For each cluster, we trained and tested a model on data from that cluster. We also tested this model on the other cluster data. For example, we trained a model on U1 and tested on each of the other clusters (U2 – U5) as well as the entire dataset (All). We performed this procedure separately for the positive and negative valence states as well as for the usage and demographic clusters¹.

¹ Similar results for other slices can be found using this code (link).

4.4 Results

We examined the generalizability of our models using the procedure in Section 4.3. If our models generalized well, we expect to see a model trained on one group perform similarly well when applied to other groups (Table 3). This was the case for the usage clusters, where the maximum difference between testing on one cluster and testing on another is 0.05. The demographic clusters were more varied. In this case, the greatest difference between testing on the one cluster and testing on another was 0.09.

Recent metrics proposed in slicing analysis, such as [7], apply to classification problems and not the regression task considered here. To better quantify model generalizability, we defined an *individual advantage* metric. Using the procedure from Section 4.1, we trained a model using the training set X and tested the model using the testing set Y . We represented the performance of the model, which is the average Spearman correlation, as $P_{X,Y}$. For a target group T , we defined the individual advantage metric as $(P_{T,T} - P_{All,T})/P_{All,T}$. This describes the proportion improvement over using a general model for the target group T . Therefore, a perfectly generalizable model would have an individual advantage of 0 since an individual model and general group model will have the same accuracy.

We used this metric to quantify the generalizability of our models. Both positive and negative models showed small, positive individual advantage values (mean usage 0.04; mean demographics 0.02), which indicates a small advantage to training cluster-specific models compared to a general model.

5. SAMPLE SIZE SIMULATIONS

We then investigated whether sample size affects the advantage for using individual models. Specifically, are individual advantages mitigated when more data is available? To address this question, we computed the average individual advantage metric over 10 cross validation folds for a range of sample sizes starting at 500. For each sample size, we randomly selected the appropriate number of instances from the training sets. We incrementally increased the sample size by 200 until we reached the actual group size, which varied between 1,500 and 7,100. We repeated this simulation 1,000 times and calculated the 95% confidence interval of the mean individual advantage metric at each sample size (Figure 1).

Table 3. Mean correlation of positive valence models (negative in parentheses) for usage clusters.

Figure 1. Averaged individual advantage simulation scores for usage clusters

We first noted that the scores for models using sample sizes less than 1,500 varied wildly, as indicated by the width of the confidence intervals in this region. As such, we can only conclude that results obtained from small samples might not be reliable. This is concerning since previous work used sample sizes ranging from 20 to 646 students [9]. As expected, for larger sample sizes, the models quickly stabilized and produced more reliable scores.

For most clusters, the individual advantage scores stabilized to a value of 0.10 or less, which indicates a small advantage of training cluster-specific models. The scores for clusters D1 and U1 seemed to increase as the sample size increased, but we cannot make strong conclusions since the sample size of these clusters was small.

6. DISCUSSION

In an attempt to answer the call for predictive generalizability [7, 10, 26], we used interaction data from 69,174 students over an entire school year to study the extent to which sensor-free affect detectors generalize across usage and demographic clusters.

6.1 Main Findings

We found that students primarily differed in their interaction rate, active semester, and primary device. The demographic clusters were primarily discriminated by grade level, F/R lunch eligibility, and (to a smaller extent) race. Using cluster membership as the only training feature resulted in near-zero results, which shows students in a particular cluster are not generally predisposed to certain affective states. We must then consider the context of a student's activity when predicting their immediate affective state.

Similar to previous work [1, 4, 9, 17, 23, 24, 27, 28], we examined the generalizability of our models by training cluster-specific models and testing them on the other clusters. We found that cluster-specific models perform slightly better on the target cluster, with a maximum difference of 0.05 for the usage clusters and 0.09 for the demographic clusters. We expanded this analysis by introducing an individual advantage metric, which measures the advantage given to a target group compared to a general (entire population) model. This metric agreed with our initial analysis by showing a small advantage given by training a cluster-specific model. The maximum advantage was 0.14 for the usage clusters and 0.11 for the demographic clusters. Although these results provide evidence that cluster-specific models are better at predicting affective valence, it is not clear what difference is meaningful in practice.

Lastly, we investigated how model generalizability changes in response to sample size. We performed a series of simulations that trained affect-detection models and systematically varied sample sizes. Models trained on 1,500 samples or less did not generate stable scores or predictions, even after 1,000 iterations. When considering sample sizes greater than 1,500 that yielded reliable scores, we found that the individual advantage scores stabilize as sample size increases at a value of 0.10 or less, which is consistent with our initial analysis. This suggests that generalizability is not greatly affected by sample size beyond the 1,500-sample threshold.

6.2 Limitations and Future Work

The greatest area of improvement is the overall model performance. As discussed in [9], the average performance corresponds to a small-sized effect. This is likely caused by the limited number and extreme generality of the training features. Future work can address this by introducing more platform-specific features, such as which quiz a student was attempting. We can then see if our models have the power to distinguish between individual affective states rather than simply identifying positive or negative valence. Of course, the use of these features will result in more platform-specific models, which limits their generalizability to different platforms or even to other domains within the sample platform.

Our analysis of generalizability was limited to demographic features and overall interaction with the Algebra Nation platform. This analysis should be extended to include other academic subjects, time frames, and regional groups. For example, while Florida does reflect the overall demographic composition of the United States, other states do not. It would be interesting to see how our models generalize to other populations. With respect to subject generalizability, while [9] showed generalizability between Algebra and Geometry, we could see how a model for mathematics generalizes to unrelated subjects such as chemistry or music.

There are several exciting opportunities to apply these large-scale sensor-free affect detectors. First, we will be able to develop real-time interventions based on predictions of a student's affective state and promote more a more engaging experience with the curriculum. In addition, as we collect data from different regions and over longer time periods, we can more directly investigate the relationship between engagement and end-of-course scores.

Lastly, it is important to understand the impacts of a one-size-fits-all model on long-term student achievement. When developing interventions, one should consider possible effects if predictions of affect are incorrect. In this case, the intervention should not have any negative consequences for the student receiving it.

7. CONCLUSION

Sensor-free affect detection models provide the opportunity to provide personalized experience for large populations of students. In this work, we answered the call to investigate how these predictive models generalize between different subpopulations in the training data. We did this using a longitudinal dataset of student interaction with an online math learning platform with our groups of interest being clusters based on typical usage on the platform and demographic features. We showed that while models trained on one cluster perform similarly well when applied to the other clusters, there is a small advantage to use individual subpopulation models rather than one general population model. It is important to consider these models' differential performance and impact when deploying large-scale platforms that adapt to sensor-free predictions of individual students' affective states.

ABSTRACT

This paper addresses a key challenge in Educational Data Mining, namely to model student behavioral trajectories in order to provide a means for identifying students most at-risk, with the goal of providing supportive interventions. While many forms of data including clickstream data or data from sensors have been used extensively in time series models for such purposes, in this paper we explore the use of textual data, which is sometimes available in the records of students at large, online universities. We propose a time series model that constructs an evolving student state representation using both clickstream data and a signal extracted from the textual notes recorded by human mentors assigned to each student. We explore how the addition of this textual data improves both the predictive power of student states for the purpose of identifying students at risk for course failure as well as for providing interpretable insights about student course engagement processes.

Student State, Clickstream Data, Mentor's Notes, LDA, Time-series Modeling, Deep Learning

1. INTRODUCTION

In online universities, modeling the population of students at scale is an important challenge, for example, in order to identify students most at-risk and to provide appropriate interventions to improve their chances of earning a degree in a timely fashion. In this respect, a plethora of approaches for clickstream analysis [11, 21, 22] have been published in

the field of Educational Data Mining, which address questions about modeling student course engagement processes [19]. While clickstream data is the most readily available, and while some success has been achieved using it for this purpose, its low level indicators provide only glimpses related to student progress, challenges, and affect as we would hope to observe and model them. In this paper, we explore the extent to which we may achieve richer insights by adding textual data to the foundation provided by clickstream data.

One advantage to modeling student behavior and states from a for-pay platform is that the level of support provided to students is greater than in freely available contexts like Massive Open Online Courses (MOOCs), and this more intensive engagement provides richer data sources that can be leveraged. In our work, we make use of a new data source provided by the Western Governor's University (WGU) platform, where each student is assigned a human mentor, and the notes from each biweekly encounter between student and mentor are recorded and made part of the time series data available for each student. Thus, even if we do not have access to the full transcript of the interactions between students and their mentors, we can leverage the documentation of provided support in order to enhance the richness and ultimately the interpretability of student states we may induce from other low level behavioral indicators we can extract from traces of learning platform interactions.

A major thrust of our work has been to develop a technique for leveraging this form of available textual data. We refer to this data as *Mentor's Notes*. In particular, we propose a sequence model to integrate available data traces over time, **Click2State**, which serves a dual purpose. The first aim is to induce predictive student states, which provide substantial traction towards predicting whether a student is on a path towards passing or failing a course. Another is to provide us with insights into the process of passing or failing a course over time, and in particular leveraging the insights of human mentors whose observations give deeper meaning to the click level behavioral data, which is otherwise impoverished from an interpretability standpoint.

Byungsoo Jeon, Eyal Shafran, Luke Breitfeller, Jason Levin and Carolyn P. Rose "Time-series Insights into the Process of Passing or Failing Online University Courses using Neural-Induced Interpretable Student States" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 330 - 335

In the remainder of the paper we motivate our specific work as situated within the literature. Next we present our modeling approach and a series of experiments that investigate the following three research questions: (RQ1) How can we extract information and meaning from mentors' notes about the formation of student states across time? (RQ2) To what extent does integrating a representation of topical insights from *Mentor's Notes* improve the ability of a time series neural model to predict whether students are on a path towards passing or failing a course? (RQ3) How can we use insights about student progress in an online course captured using student state representations from our model to understand the process of passing or failing a course? The more comprehensive version of this paper is available at Arxiv ¹.

2. RELATED WORK

One of the most important challenges in providing analytic tools for teachers and administrators [1, 19] in online university is to model the population of students in such a way as to provide both predictive power for triggering interventions and interpretability for ensuring validity. Some past research has already produced models to identify at-risk students and predict student outcomes specifically in online universities [6, 16]. For example, Smith et al. [20] proposed models to predict students' course outcomes and to identify factors that led to student success in online university courses. Eagle et al. [10] presented exploratory models to predict outcomes like overall probability of passing a course, and provided examples of strong indicators of student success in the WGU platform where our work is also situated. However, this past work has focused mainly on predictive modeling of student outcomes, whereas our work pursues both predictive power and interpretability.

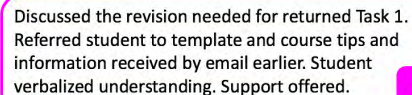

While much work in the field of Educational Data Mining explores time series modeling and induction of student state representations from open online platforms such as Massive Open Online Courses (MOOCs) or Intelligent Tutoring Systems, far less has been published from large, online universities such as WGU, which offer complementary insights to the field. Student states are triggered by students' interaction with university resources, their progress through course milestones, test outcomes, affect-inducing experiences, and so on. Affect signals in particular have been utilized by many researchers as the basis for induced student states, as this rich source of insight into student experiences has been proven to correlate with several indicators of student accomplishments [18]. Researchers have investigated affect and developed corresponding detectors using sensors, field observation, and self-reported affect. These detectors capture students' affective signals from vocal patterns [7, 17], posture [9], facial expressions [3, 17], interaction with the platform [4, 5, 12], and physiological cues [7, 15]. Although these signals provide rich insights, the requisite data is sometimes expensive or even impractical to obtain, even on for-pay platforms such as WGU, where we conduct our research.

The bulk of existing work using sequence modeling to induce student states has focused on the data that is most readily available, specifically, clickstream data. For example, Tang et al. [21] have constructed a model to predict a set of stu-

dent actions with long short-term memory (LSTM) [13] on student clickstream data from a BerkeleyX MOOC, though the basic LSTM was unable to match the baseline of defaulting to the majority class for samples of student actions. Fei et al. [11] proposed a sequence model to predict dropout based on clickstream data using recurrent neural network (RNNs) model, with more success. Wang et al. [22] also built a neural architecture using a mix of convolutional neural network (CNN) [14] and RNN for dropout prediction from clickstream data. Though these models have achieved differing success at their predictive tasks, a shared shortcoming is the lack of interpretability in the induced student state representations. Our work extends previous studies by proposing a model that enriches temporal signals from clickstream data using the textual mentor's notes to provide a means for interpreting student state representations.

3. DATA

Our study is based on data collected by Western Governor's University (WGU), an online educational platform ². To support self-paced learning, students in WGU are assigned to a program mentor (PM). The PM is in charge of evaluating a student's progress through their degree and helping to manage obstacles the student faces. A PM and a student generally have bi-weekly live calls, but this may vary depending on the student's needs and schedule. Each PM writes down a summary of what was discussed, which we refer to as a mentor's note. An example is given in Figure 1. Mentor's notes describe the status and progress of the student and what types of support was offered or what suggestions were made during the call. This information can provide meaningful cues to infer student states over time.

Discussed the revision needed for returned Task 1. Referred student to template and course tips and information received by email earlier. Student verbalized understanding. Support offered.

Figure 1: An example of mentor's notes.

In this work we specifically investigate how the use of the mentor's note data alongside the more frequently used clickstream data might enable that important goal. Clickstream data in WGU also provides us with information on how active students are and where in the WGU platform they spend their time. We collect clickstream data from four different types of web pages in the WGU platform: course, degree plan, homepage, and portal. The course web pages cover all pages related to courses in WGU. Degree plan represents a dashboard where students check their progress toward a degree. Homepage is the main page that shows students' progress in each course and allows access to all provided WGU features. Portal covers any other pages for student support including technical and financial assistance.

An example of the clickstream data can be seen in Table 1. Each row represents one of five different click sources: target course page, other course page, degree plan page, portal page, and homepage. We divide the course pages into "target course" and "other course". Each column represents one of different six click types: click count (C1), focus state count (C2), keypress count (C3), mousemove count (C4), scroll

¹<http://arxiv.org/abs/1905.00422>

²<https://www.wgu.edu/>

count (C5), and unfocused state count (C6). The values in the table represent the weekly count of different type of clicks from each different source.

For this paper, we have collected the mentor’s notes and clickstream data from two courses conducted in 2017: Health Assessment (HA) and College Algebra (CA). We choose these two courses because they are popular among students and represent different levels of overall difficulty. Table 2 shows the statistics for the dataset. “Average prior units” is the average number of units students transferred to WGU from prior education when they started the degree, and functions as a proxy for the level of student’s prior knowledge. We split the dataset for each course into a training set (80%), a validation set (10%), and a test set (10%). For training, to avoid a tendency for trained models to over-predict the majority class, we have resampled the training set so that both the pass state and the fail state are represented equally.

	C1	C2	C3	C4	C5	C6

Avg length of notes (chars)	198 ± 47	194 ± 55

Table 2: Data Statistics

4. PROPOSED METHOD

As we have stated above, in our modeling work, we propose a sequence model, **Click2State**, with two primary purposes. The first is to form a student state representation that will allow us to better identify students at risk of failing a course than a baseline model that does not make use of rich textual data. The second is to provide us with a means to interpret the meaning of a student state representation.

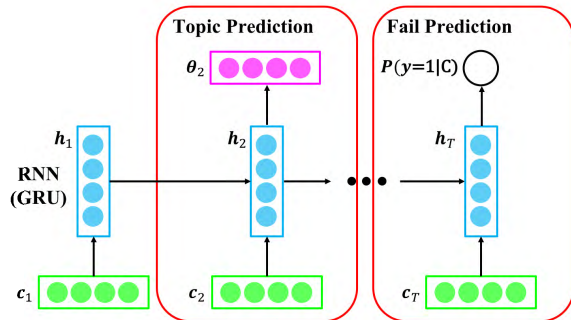

Figure 2: Architecture of Click2State Model.

Figure 2 provides a schematic overview of our proposed model. Note that it is first and foremost a sequence model that predicts whether a student will pass or fail a course

based on an interpretable student state that evolves from week to week as each week’s clickstream data is input to the recurrent neural model. A summary of the content of the mentor’s note for a week is constructed using a popular topic modeling technique, specifically Latent Dirichlet Allocation (LDA) [2]. In the full model, an intermittent task to predict the topic distribution extracted from the mentor’s notes associated with a time point is introduced. The goal is to use this secondary task to both improve the predictive power of the induced student states over the baseline as well as to enhance the interpretability of the state representation.

Feature Vector Design We train our model using clickstream feature vectors (as input) and topic distribution vectors (as output for the topic prediction task). We design the clickstream feature vector to include both an encoding of click behavior of students from a time period as well as a control variable that represents the prior knowledge of students as estimated by the number of units they were able to transfer in. The full clickstream feature vector contains thirty weekly counts for each different type and source of click, in addition to the single control variable just mentioned, which is the number of transferred units. We use min-max normalization to scale the values between 0 and 1. To extract a topic distribution vector for each mentor’s note, we run Latent Dirichlet Allocation (LDA) over the whole set of mentor’s notes from the entire training dataset.

Formal Definition of the Model Denote the student’s clickstream features by $C = (c_1, c_2, \dots, c_T)$, where c_t is the clickstream feature vector of t th week, and T is the number of weeks for the term. The clickstream feature vectors are encoded via Gated Recurrent Units (GRU) [8], which are variants of the Recurrent Neural Network (RNN). At each time step t , this network constructs a hidden state of the student for the t th week, $h_t \in \mathbb{R}^H$, where H is the dimensionality of the hidden state. We consider h_t as the student state representation at t th week. Based on the generated student state representation from RNN (h_t), our model is trained to predict a topic distribution of a mentor’s note and the probability of the student failing that course.

Topic Prediction Given the generated hidden states from RNN (h_t) for the t th week, the model estimates the true topic distribution ($\theta_t \in \mathbb{R}^{N_t}$) of a mentor’s note on t th week where N_t is the number of topics. The estimated topic distribution ($\hat{\theta}_t \in \mathbb{R}^{N_t}$) is computed by taking h_t as an input of one fully connected layer (weight matrix: W_θ) whose output dimensionality is N_t followed by a softmax layer.

$$\hat{\theta}_t = \text{Softmax}(W_\theta h_t)$$

Fail Prediction As data from a student’s participation in a course is fed into the RNN week by week, the model estimates the probability of the student failing that course ($P(y = 1|C)$) at the last timestep T . The estimated probability is computed by taking h_T as an input of one fully connected layer (weight matrix: W_y) whose output dimensionality is one followed by a sigmoid layer.

$$P(y = 1|C) = \text{Sigmoid}(W_y h_T)$$

Loss The loss function is composed of KL divergence loss for the topic prediction and binary cross-entropy loss for the fail prediction. Assume there are a total of N students. The

KL divergence loss of topic distribution of the mentor's note for n th student at time t is defined as:

$$KLD_{n,t} = D_{KL}(\theta_{n,t} \parallel \hat{\theta}_{n,t}),$$

where $\theta_{n,t}$ and $\hat{\theta}_{n,t}$ are the true and estimated topic distribution of the mentor's note at time t for n th student. The binary cross-entropy of the n th student measures the similarity between $P(y_n = 1|C)$ and the true y_n as:

$$BCE_n = -y_n \log P(y_n = 1|C) - (1 - y_n) \log(1 - P(y_n = 1|C)),$$

Assume that there are a total of N_n mentor's notes for n th student. Combining the two losses, our final loss is

$$\frac{1}{N} \sum_{n=1}^N [\lambda BCE_n + (1 - \lambda) \frac{1}{N_n} \sum_{t=t_{n,1}}^{t_{n,N_n}} KLD_{n,t}],$$

where $t_{n,i}$ is the timestep when n th student has i th mentor's note, and λ is the rescaling weight.

5. RESULTS

In this section, we answer our aforementioned research questions one by one with the experiment results.

RQ1. What types of information about student states can we extract from mentor's notes? We answer the question of how student state information may be extracted from mentor's notes through application of LDA to the notes. We set the number of topics to ten to maximize the interpretability of the results. Table 3 shows the learned topics with manually assigned labels, topical words, and text. Topical words are the top ten words with the highest probability of appearing within each learned topic, and are presented in decreasing order of likelihood. The topical text column contains an example snippet from one of top ten mentor's notes for each topic. We exclude the one topic that was incoherent out of the 10 learned topics.

Note that there are four topics related to student progress and plan, term plan (T5), course progress (T6), term progress (T7), and goal setting (T9). Course progress and goal setting (T6, T9) focus on progress towards modules in a particular course, along with past and present goals about the course itself. Term plan and term progress (T5, T7) emphasize discussions about plans for a term, such as courseload within in a term, course selection, and long-term degree planning. There is a clear utility to these topics as an interpretation tool for regulation of the student's process moving through the curriculum—if a student hits an impasse, mentor's notes are expected to focus on what challenges the student experienced and how to address these challenges.

The remaining six topics provide insight on specific issues and circumstances a student may be facing at a particular time, and which may end up impacting their overall progress. In revision (T1), we discover students seeking feedback on revisions, suggesting significant engagement with the platform. In question (T2), students ask for tips on using WGU platforms, course logistics, and how to succeed in a given course. In time constraint (T8), students point out time constraints in their daily life to explain why goals were not met. The time constraint (T8) topic may explain

abnormal absence or dropout. Assessment (T3) contains the result or plan of assessments and review for exam (T4) includes progress or plans of review for exam preparation.

RQ2. Does the task of topic prediction construct better student state representation than our baseline, as evaluated by the ability to predict student failure? We measure the predictive power of learned student state representation from our model and compare with that of our baseline, which shares the same neural architecture but is not trained on the extra task of topic prediction. The specific predictive task is to determine whether a student fails a course within a given term given a sequence of weeks of student clickstream data. We trained separate models to make a prediction after a set number of weeks so that we could evaluate the difference in predictive performance depending on how many weeks worth of data were used in the prediction. We measure the AUC scores of our model and baseline using data from two WGU courses: Health Assessment (HA) and College Algebra (CA).

Figure 3(a) shows the AUC scores across time steps for the HA course while Figure 3(b) shows the AUC scores across time steps for the CA course. For HA, our model achieves a statistically significant improvement (p-value < 0.05) in performance over the baseline model after the 5th week. For CA, our model achieves a statistically significant improvement after the 17th week. This difference in model performance between the HA and CA courses suggests the result from CA-specific topic data adds limited predictive power to the model. It is possible the clickstream data of students taking CA already contains enough information about whether a student is going to fail, a conclusion supported by the fact that AUC scores of the baseline model for CA are always better across time steps than those for HA.

Figure 3(c) exhibits the minimum KL Divergence loss of our model across time steps to determine how well our model is predicting the topic distribution of each mentor's note for each course. Though we determined that adding this task improves the fail prediction task, results on this task specifically are not impressive, demonstrating the relative difficulty of predicting mentor's notes from click data.

RQ3. What insights do we gain about the process of passing or failing a course over time from predicted mentor's notes topic distributions over time from the model? We perform two different experiments on the dataset of clickstream and mentors' notes data of students taking the College Algebra course. We choose this course because our topic prediction loss was lower (and thus, accuracy higher) for the course. First, we determine what topics inferred from our model correlate with whether a student will pass or fail a course. Then we find sequences of standardized topic probabilities of each topic inferred by our model that characterize students likely to pass or fail.

State	Assessment	Course progress	Term progress
P	-0.1486	0.6301	0.2298
F	0.1735	-0.0049	-0.1647

Table 4: Standard Score of Inferred Topic Probabilities from P and F State

Topic	Topical Words	Topical Text
T1. Revision	task, submit, revise, discuss, equate, complete, need, write, practice, paper	The ST and I discussed his Task 3 revisions after he made some corrections. The ST still needs to revise the task based on the evaluator's comments. He plans to do more revisions that align with the task rubric and submit the task soon.
T2. Question	student, question, call, email, send, course, discuss, appoint, speak, assist	Student emailed for help with getting started. CM called to offer support. Student could not talk for long. CM emailed welcome letter and scheduling link and encouraged for student to make an appointment
T3. Assessment	week, goal, today, schedule, pass, take, exam, final, work, talk	C278: took and did not pass preassessment, did not take final . NNP C713: took and did not pass the preassessment. Passed LMC1 PA with a 65 on 02/27. LMC1 exam scheduled for 02/27
T4. Review for exam	student, review, assess, plan, study, attempt, discuss, complete, take, report	Student scheduled appointment to review for first OA attempt but had taken and not passed the attempt by the time of the appointment.
T5. Term plan	student, discuss, course, complete, engage, college, term, plan, pass, progress	Discussed final term courses . Discussed starting C229 and working through hours and then working through C349 course .
T6. Course progress	goal, course, progress, current, complete, previous, work, date, pass, module	Current course : C349 Previous goal: completed modules 1-3 and engage shadow health by next appt date Progress toward goal: Yes New Goal: shadow health completed and engaged in video assessment
T7. Term progress	term, course, complete, date, goal, week, progress, current, leave, remain	Date: 8/22/17 Term Ends: 5 weeks OTP Progress : 5/14 cu completed Engaged Course : C785 Goal Progress : did not pass PA
T8. Time constraint	work, week, lesson, complete, go, progress, plan, finish, time, goal	NNP stated he was not able to make forward progress in course related to personal situation and time constraints from an unexpected event.
T9. Goal setting	goal, week, work, complete, task, progress, pass, accomplish, finish, contact	Previous goal : finish shadow health, finish and submit video by next call, start c228 next Progress /concerns: states working on c349 SH, discussed deadlines Goal : finish shadow health

Table 3: LDA Topics Learned From Mentor's Notes

(a) Fail Prediction Performance on HA

(b) Fail Prediction Performance on CA

(c) Topic Prediction Performance

Figure 3: Performance of Fail and Topic Prediction

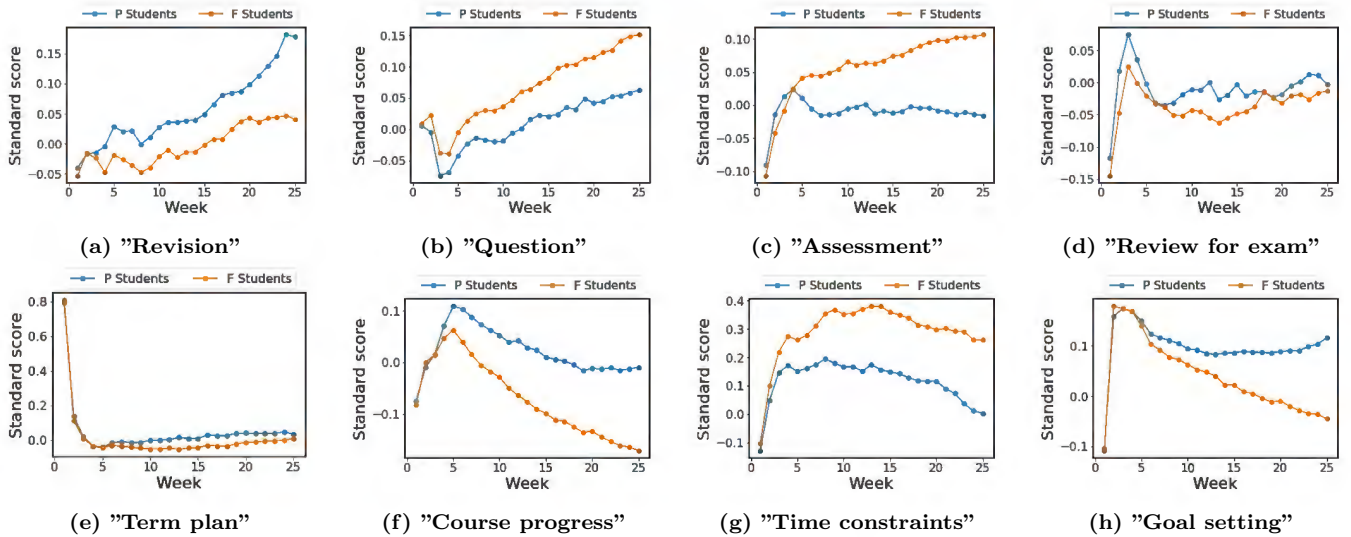

Figure 4: Standard Score of Each Topic Probability across Weeks for P and F Students

Experiment 1. In the first experiment, we find the two student state representations which minimize or maximize the probability of failing a course. We call the state representations that minimize and maximize the probability of failure as a P state and F state. Then, we show what topic distributions are inferred from each state. We represent emphasis, or a lack thereof, on a topic by standardizing topic probabilities and observing the number of standard deviations above and below the mean of a topic probability (standard score).

Table 4 shows the standard score for inferred topic probability from the P and F state. We only present the standard score of topics that vary wildly between P and F state. For example, the standard score of assessment topic (T3) for the P state is negative and for the F state is positive. One interpretation is that students likely to fail have more trouble in passing assessments, and thus talked to their mentors more about assessment topic (T3). The standard score of course and term progress (T6, T7) for the P state is positive and

negative for the F state, which shows students likely to pass report smoother progress instead of ongoing issues.

Experiment 2. We compare the trajectory of inferred probability of each topic by our model from students who passed (P students) and failed (F students) a course. Figure 4 shows the average standard score of topic probability per topic for P and F students over time.

We can see through this experiment clear, distinct patterns for the frequency of each topic over time that make intuitive sense given the format of online courses. For example, term plan (T5) is high frequency for the first week and plunges right after, since most students and mentors will naturally discuss plans for a term at the start of each term. The standard scores of other topics related to goal and progress (T6,T7,T9) also decrease over time, likely for similar reasons; the plot for T7 is omitted to save space, but it shows the similar pattern as T6. The standard scores of revision (T1), question (T2), and assessment (T3), meanwhile, increase over time, which may indicate students seek help more actively as they approach the end of a term. The standard scores of review for exam (T4) increase dramatically until the third week, decrease for few weeks, and finally level off. As the only condition for students in WGU to pass a course is to pass the final assessment, it may be that many students take their final assessments during the earlier weeks so they can pass a course as early as possible. The standard scores of time constraints (T8) steeply increase until the fourth week, and then gradually decrease over time. This suggests that when students begin a term they do not expect to have time constraints, but accumulate unanticipated issues in their personal lives as the course goes on.

For most topics, the P and F students exhibit distinct divergences in topic patterns. For topics related to goal and progress (T6, T7, T9), the gap between P and F students increases over time—suggesting that as time goes on F students will be reporting obstacles to their mentors instead of positive progress. The gap between P and F students for question (T2) increases over time, likely for similar reasons. For revision (T1), P students generally have higher standard scores than F students over time, supporting the idea that P students actively seek opportunities for revision towards the end of a term. For assessment (T3), standard score for F students increases over time while score for P students decreases. This could suggest that F students are more likely to procrastinate and struggle with their assessments than P students. Finally, for time constraints (T8) F students show higher standard score as time goes on. A likely interpretation is that students who encounter time constraints cannot devote focus to a course and are more likely to fail.

6. CONCLUSION

In this paper, we propose and evaluate a sequence model, **Click2State**, which aims to build an interpretable student state representation by leveraging mentor’s notes to give deeper meaning to impoverished clickstream data. We also introduce a methodology for interpreting the learned representation from our model that extracts time-sensitive insights about the process of passing or failing a given online course. Our experimental results demonstrate that student state representations learned by our model have better pre-

dictive power on the task of determining student failure rate than a baseline that only uses click stream data. We also present how individual topic-based insights into the process of passing or failing a course let us construct a rich characterization of a student likely to fail or pass an online course.

ABSTRACT

Collaborative problem-solving (CPS) as a key competency required in the 21st century. There has been an increasing need to understand CPS since it involves not only cognitive but also social processes, and thus its process is difficult to examine. Recent research has highlighted that computer-based learning environments provide an opportunity for students to collaborate with others to solve scientific problems and facilitate their knowledge building process, which can be dynamically tracked within the systems. However, limited research has attempted to identify CPS process captured in the computer-based learning environments designed for supporting CPS. This study therefore aimed to investigate students' CPS process in a serious game, *Alien Rescue*, by analyzing a student's daily tool use action sequence generated in the game. First, we computed a daily gameplay action similarity among students in a group using a similarity coefficient, *Jaccard* (*Jac*). Each group's *Jac* coefficients over the entire gameplay period (i.e. six days over three weeks) were considered as the group action similarity trajectory. The *Jac* coefficient of each day was entered as a single feature (i.e. a total of six features) to conduct a *KmL* cluster analysis that clusters longitudinal data. Three clusters of groups with similar behavior traits (i.e. group action similarity trajectories) were identified. The groups' background information (e.g. solution scores, knowledge gain scores) further provided how the groups' CPS traits can be related to their learning performance.

Keywords

Collaborative problem-solving, learning process, serious game, *Jaccard* coefficient, *KmL* cluster analysis, science learning.

1. INTRODUCTION

Research has highlighted a need for a comprehensive understanding of collaborative problem-solving (CPS), which is

regarded as one of the critical competencies of the 21st century skills [10]. OECD [21] recently defined CPS competency as "the capacity of an individual to effectively engage in a process whereby two or more agents attempt to solve a problem by sharing the understanding and effort required to come to a solution and pooling their knowledge, skills and efforts to reach that solution." Computer-based learning environments offer opportunities to monitor collaborative process in order to engage learners in building a shared understanding of a complex problem and support them in knowledge construction process by providing prompts to respond to their learning process or triggering real-time interventions to improve their CPS process [23, 25]. The captured log data including temporal and spatial students' behaviors within the system can reveal emergent patterns that not only reflect individual and group behaviors during CPS activities within the system, but also engage groups with diverse behavior patterns in an effective CPS process accordingly. Despite of these benefits, scanty research has attempted to examine collaboration process captured within a computer-based learning environment designed for supporting CPS. In addition, research on CPS has been mostly conducted by investigating verbal communications (e.g. [13]).

To address this gap, this study aims to investigate groups' CPS process in a serious game, *Alien Rescue*, using an individual student's daily tool use action sequence generated during the entire gameplay period (i.e. a total of six days over three weeks). We used a similarity coefficient, *Jaccard* (*Jac*), to calculate a daily gameplay action similarity among students in a group. *Jac* coefficients of each group over the entire gameplay period, serving as the group's action similarity trajectory, were used to identify patterns of group action similarity trajectory. The findings provide empirical evidences of diverse patterns of CPS process emerged as students engaged in their CPS activities in the serious game. Further, we discuss design considerations of serious games and how our application of the methods can be applied to future studies.

2. RELEVANT WORK

2.1 Collaborative Problem-Solving Process

CPS process has become a field of interest among researchers with the potential to get a better understanding of CPS activities. A review of recent research revealed that CPS phases and synchrony were two topics central to the research on CPS process. Researchers have identified several phases of CPS activities. Informed by

Jina Kang, Dongwook An, Lili Yan and Min Liu "Collaborative problem-solving process in a science serious game: Exploring Group Action Similarity Trajectory" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 336 - 341

dynamical systems approaches (e.g. [1]), researchers [29] investigated problem-solving phase transition by identifying an entropy peak in transition between the phases including knowledge construction, group problem model, group consensus, and evaluation (see more details in [6]). The entropy peak corresponds to shifts in communication in a problem-solving process within a group. The results showed empirical evidences that groups exhibit phase transitions during their CPS. The concept of initiative has been considered as another way of investigating CPS phases. Howard, Di Eugenio, Jordan, and Katz [11] examined *task initiative* shifts during CPS, which is one type of initiatives and refers to the participation of people in a conversation and their contributions to problem-solving activities during the conversation. They found that group members took *task initiative* when attempting at adding new contents which help the members to advance problem-solving.

Synchrony is another critical factor in understanding CPS process. Synchrony can be developed as group members reach out a shared problem space, which leads to potential transformation or advancement in their problem-solving process. Mercier and Higgins [18] elaborated on the concept of “a joint problem space” [20] and highlighted the importance of a joint understanding of the problem, which can be successfully developed when group members all come to understand the problem that has been worked on. The effectiveness of group work is related to the convergence of the individual members’ mental models [4]. Cukurova, Luckin, Millán, and Mavrikis [3] illustrated the significance of synchrony among group members. They provided the evidence of a positive relationship between CPS competence and member synchrony; that is, high competence CPS groups tended to have high levels of member synchrony.

2.2 Similarity Coefficients in Serious Games Analytics

A similarity measure is a statistical method to determine how (dis) similar one object is from the other ones by quantifying the similarity or distance between the objects. Typically, the objects being compared can be text strings, audios, images, videos, and navigation sequences, etc. Mathematically, a similarity metric is measured within the range of 0 to 1, indicating two objects are identical (1) and completely different (0). Various applications of similarity measures have been applied in emerging fields of technology, such as audio match and facial recognition. There are five most commonly used similarity measures, namely, Dice, Jaccard (*Jac*), Overlap, Cosine, and the Longest Common Substring coefficients (see details in [15]). In this paper, we used *Jac* coefficient. The use of *n*-gram is an indispensable step to calculate a similarity coefficient, when the directionality or contexts between objects is an important concern [15]. By using *n*-gram, researchers are able to set the sequence of objects before the calculation of similarity coefficients. The *n*-grams are named by the size of the sliding windows used—hence, unigram ($n = 1$), bigram ($n = 2$), trigram ($n = 3$), and fourgram ($n = 4$) and so on.

A serious game has shown its support to improve learners’ CPS performance with the chance to develop problem-solving and collaboration skills and with higher learning motivation (e.g. [25]). As players’ actions and behaviors in serious games are considered as the evidence in understanding CPS processes, researchers take serious games as the tool to observe and infer the players’ decision-

making process (e.g. [15]). Similarity coefficients have been applied to investigate the players’ gaming process. Osborn and Mateas [22] defined a (dis) similarity metric for the comparison of players’ sequences of actions. They found that the tool *Gamalyzer* (an exploratory visualization of gameplay traces) with the proposed (dis)similarity metric is valid in visualizing the overall strategies of game players. Learning performance in serious games can be quantified with the application of similarity measures to compare the course of action between novice and expert players (e.g. [16]). Loh et al. [15] examined several commonly used similarity measures to determine which measure or combination of measure would be viable in differentiating novice from expert players in serious games. Their findings showed that combining different similarity measures showed stronger predicting abilities than using a single similarity.

3. METHODS

3.1 Participants

The participants included sixth graders ($n = 196$) from a middle school in the Southwestern area of the United States. The participants played a serious game, *Alien Rescue*, as a part of science curriculum over three weeks. The teachers encouraged students to group between 2-4 students, but also allowed students to work individually during the gameplay period. There was a total of 70 groups. Each student in a group used their own laptop and solved the problems in collaboration with group members by collecting required information and eliminating planets or moons to find out the most suitable homes for each alien species. In order to investigate students’ collaborative problem-solving process, we only included students who worked in a group ($n = 156$). The students were balanced in terms of gender (77 males and 79 females). At-risk¹ students comprised 51.3% of the sample.

3.2 Serious game

Alien Rescue (<http://alienrescue.edb.utexas.edu>) is an open-ended serious game that allows students to discover multiple pathways to solve a problem [9]. In this game, students play in the role of young scientists who are asked to join the United Nations in the effort to rescue six alien species displaced from different places in a distant galaxy by helping them to find new homes in our solar system. Students are engaged in scientific investigations without explicit guidance in their problem-solving process. Students are able to develop a mastery by trying out multiple ways of solving the problem, such in finding evidence, matching information, and formulating rationales. Students develop high-level cognitive skills (i.e. goal setting, hypothesis generation, problem-solving, and self-regulation) while exploring the game environment. The previous studies (e.g. [12, 14]) showed empirical evidences of problem-solving stages within the game; that is, initial exploring and problem identification, background research including gathering and integrating information, hypothesis generation and testing, and solution generation. A set of cognitive tools are provided in the game to support students’ problem-solving process (see more details of each tool in [14]). Students are challenged to identify relevant information of the solar system by using in-game cognitive tools and match the information with each alien’s needs and characteristics. To solve the complex and ill-structured problem, students need to use the tools strategically. Students get access to the cognitive tools through a two-layer interface. Tools in first layer

¹ The school identified students as being at-risk of dropping out of a school by the state-defined criteria including low-performance

on an assessment instrument and limited English proficiency [27].

can be accessed one at a time while the six tools in the second layer can be used anytime overlaid with other tools (see Figure 1).

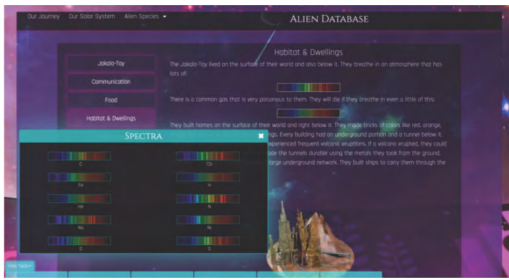

Figure 1. Alien Database overlaid with Spectra

3.3 Data sources

3.3.1 Performance scores

Before and after gameplay, an individual student's comprehension of factual and applied scientific knowledge introduced in the game was measured using a Space Science Knowledge Test (SSKT). SSKT consists of twenty-four multiple choice items (Cronbach's $\alpha = 0.77$), which score ranges between 0 and 24 (1 point for each item) logged in the system. An individual student's SSKT gain score was calculated by subtracting the pretest score from the posttest score. Then, each group's average gain score was calculated (i.e. total gain scores / a number of students in a group), which is considered as each group's after-game performance.

In addition, the game logs a student's written recommendation(s) for each alien, in which they must indicate an appropriate home for each species and provide a rationale. Students can submit multiple recommendations for each alien species, which reveals the results of students' problem-solving processes—that is, justifications of their solutions using the gathered data during the gameplay. The solutions were evaluated using an 8-point rubric used in previous studies (see more details in [2]) in terms of the correctness of the solution and the number of reasons to the selected home. Each group's average solution score is considered as the group's in-game performance.

3.3.2 Gameplay data

The gameplay data—that is, the user-generated data derived directly from students' actions within the game—were used to identify students' navigation patterns as they engaged in *Alien Rescue*. The game logs every action as each student interacts with the environment. The gameplay data contains a student identifier, a cognitive tool that the student accessed, a type of action (e.g., open, close, click), an additional note on student's interactions, and a timestamp for each action (see an example of data in Table 1). "Open" indicates a student opens a tool, while "Click" indicates a student clicks a submenu of the tool.

Table 1. Example of A Student's Navigation Data

Tool	Action	Notes	Timestamp
Probe Design	Open		5/17 10:33:19
Solar System	Click system	Mercury	5/17 10:36:48
Concepts	Open		5/17 10:48:00
Concepts	Close		5/17 10:49:06

3.4 Analysis

3.4.1 Group action similarity using a Jaccard coefficient

We computed a gameplay action similarity between students in a group with a *Jac* coefficient (see 2.2). In order to calculate the similarity of students' navigation traces for each day, we cleaned and transformed each student's navigation data into a 'bag of words.' For example, assuming that on Day1, one student's navigation is represented by *string A* = "Probe Design Open, Solar System Click Mercury, Concepts Open, ...", and the other student's data is expressed by *string B* = "Solar System Open, Solar System Click Mercury, Solar System Click Venus, ...", we can obtain the intersection set of *A* and *B* ($A \cap B$) and union set of *A* and *B* ($A \cup B$). The *Jac* coefficient is therefore the length of intersection set over the length of the union set. In order to check if there is a directionality between students' actions, we also applied a bigram setting to the navigation sequence and calculated a *Jac* coefficient. A bigram sequence was obtained using a 'sliding window' of size 2. We conducted a descriptive analysis to compare the distributions of the unigram with bigram *Jac* coefficients of all groups. As shown in Figure 2, the groups' unigram *Jac* coefficients were overall normally distributed, while the bigram *Jac* coefficients showed highly skewed to zero (i.e. small variance). Therefore, we decided to use a unigram *Jac* coefficient for this study. As Loh et al. [15] suggested using a larger *n*-gram, when any contextual relationship between actions are critical, we included a type of action (see 3.3.2) and split the data into each day to further consider the context and directionality.

Figure 2. Histograms of unigram and bigram *Jac* coefficients

Note. Unigram ($M = .42$, $SD = .24$), Bigram ($M = .12$, $SD = .21$)

3.4.2 Clustering analysis for longitudinal data

A *Jac* coefficient of each day was entered as a single feature (i.e. a total of six features) to conduct a cluster analysis to identify the potential clusters of collaborative groups with similar behavior traits (i.e. group action similarity trajectory). Six *Jac* coefficients of one group can be seen as the action similarity trajectory of the group over the gameplay. To handle such trajectory data, we used a *KmL* package in R, which is a new implementation of *k*-means designed to analyze longitudinal data [8]. One common problem in longitudinal studies is missing data (e.g. [17]). While *k*-means is unable to handle missing values and normally excludes missing data, *KmL* provides diverse imputation methods (e.g. linear interpolation, copyMean; see more details [7]) to deal with different types of missing values including intermittent missing data (data missing in the middle of a trajectory) and monotone missing data (data missing either at the beginning or end) [19]. We were unable to calculate a coefficient when there was only one student in a group logged in the game on a certain day. There were such missing

values found randomly over six gameplay days. Therefore, we used linear interpolation (Bisector) to handle missing values of the *Jac* dataset, since the method considers not only a local intermediate line (not just sensitive to first or last values), but also a bisector between a global and local lines.

KmL provides methods to define starting conditions and an optimal number of clusters and an easy way to run several *k*-means. *KmL* transforms longitudinal data into an object called ‘ClusterLongData.’ Once the object has been created, *KmL* runs *k*-means several times and stores all the clusters that the algorithm finds over each iteration of finding an optimal partition in the object. *KmL* also offers a tool that can visualize partitions, in which researchers can make a decision on the best partition by comparing different criteria including Calinski & Harabatz, Ray & Turi, and Davies & Bouldin (e.g. [7]). In this study, 3 clusters were suggested as the optimal number of clusters.

The data failed the major assumption of the one-way ANOVA (i.e. the non-normally distribution assumption). We thus conducted a non-parametric test, Kruskal-Wallis H test, to confirm a statistical significance of the group action similarity trajectories between clusters since a cluster analysis can only reveal the latent cluster patterns. In addition, the cluster patterns were visualized for deeper understanding of group action similarity trajectories in each cluster.

4. RESULTS

As shown in Table 2, the average values of daily *Jac* coefficients as exhibited by the three clusters of groups achieved the level of significance (χ^2), indicating the groups were well-partitioned into each cluster. Kruskal-Wallis H tests overall showed that there were statistically significant differences between the mean ranks of daily *Jac* coefficients at least in one pair of clusters. Dunn’s pairwise tests for each *Jac* coefficient were carried out for the three pairs of clusters (i.e. Cluster 1 & Cluster 2, Cluster 2 & Cluster 3, and Cluster 1 & Cluster 3). We further examined the background of the groups in each cluster including the average SSKT gain score and the number of groups who submitted at least one solution. To further investigate potential patterns between the clusters, line charts of action similarity trajectories grouped by each cluster including a similarity trajectory trend were derived (see Figure 3). As shown in Figure 3, the line charts indicated that the similarity trajectory trends of the groups in each cluster were distinctively different.

Approximately 40% of the groups are centered in Cluster 1, and the mean ranks of *Jac* coefficients were overall lower than those of the other two clusters. As shown in Figure 3, this cluster’s overall

similarity trajectory decreased slightly. This cluster showed the lowest solution submission rate. These groups achieved the lower average solution scores and SSKT gain scores than the other clusters.

Figure 3. Similarity Trajectories of Groups in Each Cluster

Note. The dashed line shows a polynomial trend model of degree 2 computed for ‘Average of *Jac*’ given ‘Day’ (dotted lines for a confidence band).

About 30% of the groups are in Cluster 2, and the groups exhibited overall the highest mean ranks of *Jac* coefficients except for Day 5. Similar to Cluster 1, the groups in Cluster 2 exhibited a decreasing similarity trajectory trend toward the end of gameplay, but maintained high similarity in their group actions during the first few days. The groups in this cluster showed the highest solution submission rate. Both their average solution and SSKT gain scores showed that their average performance was close to the mean performance of all clusters.

Lastly, the rest of the groups are centered in Cluster 3. The groups in Cluster 3 exhibited an increasing similarity trajectory trend with the peak on Day 5. It is worth noting that their *Jac* coefficients during the first two days were recorded as the lowest mean ranks among all clusters. The solution submission rate of Cluster 3 is close to the average solution submission rate across all clusters (31.58%). However, the groups who submitted at least one solution performed better at their solution submissions than other clusters. Additionally, the groups in this cluster performed the best at their SSKT gain score.

Table 2. Cluster Membership Description

Cluster	Group SSKT Gain score (Mean)	^a No. of groups with solution(s)	<i>Jac</i> Day1	<i>Jac</i> Day2	<i>Jac</i> Day3	<i>Jac</i> Day4	<i>Jac</i> Day5	<i>Jac</i> Day6	<i>Jac</i> (Mean)
C1 (<i>n</i> = 29, 41.43%)	1.727	6 (20.69%, ^b <i>M</i> _{solution} = 2.00)	0.3057 ^d (30.12)	0.3398 (27.10)	0.2901 (20.26)	0.3079 (20.55)	0.2503 (23.98)	0.2256 (22.21)	0.2866
C2 (<i>n</i> = 22, 31.43%)	2.682	9 (40.91%, <i>M</i> _{solution} = 3.67)	0.5473 (53.84)	0.6427 (55.41)	0.6420 (52.55)	0.5982 (46.64)	0.4149 (38.02)	0.5170 (45.18)	0.5603
C3 (<i>n</i> = 19, 27.14%)	3.412	6 (31.58%, <i>M</i> _{solution} = 4.00)	0.2218 (22.47)	0.3213 (25.26)	0.4961 (39.03)	0.5785 (45.42)	0.5609 (50.16)	0.4963 (44.58)	0.4458
^c χ^2			27.73***	30.80***	32.29***	26.77***	19.49***	21.18***	

Note. ^aThe number of groups submitted at least one solution (Percentage of the groups in each cluster); ^bAverage of the total solution scores of groups in each cluster; ^cKruskal-Wallis H test results, ****p* < 0.001; ^dMean ranks

5. DISCUSSION

We applied a *Jac* coefficient to investigate CPS process within a serious game, *Alien Rescue*: that is, (1) to compute a daily gameplay action similarity among students in a group and (2) to identify action similarity trajectory patterns across groups using each group's similarity trajectory.

Although the groups in Clusters 1 and 2 exhibited overall a decreasing similarity trend, Cluster 1 showed relatively lower action similarities over the entire gameplay, indicating the group members did not use the same tools. The group members seemed to maintain the individual tool use tendency over time. Both Clusters 2 and 3 showed relatively higher *Jac* coefficients and higher in-game (i.e. solution score) and after-game (i.e. knowledge gain score) learning performances, which, together with the chi-square test, can be most likely seen there might be a potential positive relationship between a *Jac* coefficient and learning performance. However, the two clusters' *Jac* coefficients followed a different pattern; that is, the *Jac* coefficients of Cluster 3 have risen considerably over the gameplay period, and the group in Cluster 3 started off with the lowest action similarity among all clusters. Additionally, the results of Dunn's pairwise tests showed the *Jac* coefficients were significantly different ($p < .001$) between Cluster 2 and Cluster 3 only during the first two days. Research has shown the importance of the convergence of individual's mental models in CPS [4] and the positive association between CPS competence and a level of member synchrony [3]. The findings therefore suggest that, during the early gameplay days, the group members in Cluster 3 came to successfully understand the problem and engaged in their collective cognitive process. This further supports the fact that a group action similarity trajectory can be an indicator of the process of developing shared problem space between group members [18].

We applied *n*-gram to compute a *Jac* similarity coefficient: unigram and bigram. Compared with the groups' unigram *Jac* coefficients, the bigram *Jac* coefficients showed a small variance (i.e. highly skewed to zero). In this study, a unigram *Jac* coefficient is therefore a viable way in understanding different levels of group collaboration in this serious game. Research on serious games analytics highlighted the use of *n*-gram would be critical to understand directionality and contexts between events or actions [15, 28]. Since a unigram can possibly ignore the context and directionality of actions, we included a type of action (i.e. click a sub-menu in each tool) to further consider the context and split the data into each day to preserve the directionality when computing a *Jac* coefficient. Such modification is needed when applying *n*-grams to different purposes of study. In addition, we applied a bigram to further examine the frequent sequences of groups in each cluster.

KmL, a cluster analysis for longitudinal data, has been often used in scientific disciplines such in medical research [7, 8]. The *KmL* clustering results in this current study showed remarkable differences of the groups' action similarity trajectories among three clusters, which indicate different patterns of CPS process in the serious game. In particular, the positive action similarity growth of Cluster 3 demonstrated that they developed a shared understanding of the problem during the early gameplay days, which has been considered as a critical process of successful collaboration in CPS activities [5, 23]. It is confirmed by the fact that the learning performance of group members of Cluster 3 was higher than that of the groups in other clusters, indicating their experience throughout the CPS process was successfully transformed to their knowledge

gain. The findings highlight the importance of providing guidance for students who tend to work independently (i.e. Cluster 1) or who may simply replicate actions of other students in the group (i.e. Cluster 2) to engage in the process of developing a shared problem space. The results further inform design considerations of serious games that support CPS: for example, providing prompts with explicit inquiries, in which a group can be engaged in the successful CPS process grounded on the group's achievement of a shared understanding of a given problem. Taken together, this study confirms *KmL* as a promising method to examine features at different time points generated from gameplay data, which can be seen as an action trajectory that provides insights into CPS process in serious games.

Our work has limitations that should be addressed in future studies. First, the dataset is small and was collected at one middle school with little diversity; for example, 51.3% of the sample was labeled as at-risk, which may not be applicable in other schools with different settings. Second, understanding CPS process is critical, but challenging particularly in an open-ended learning environment like *Alien Rescue*. This work therefore should be expanded to include additional data such as video or audio recordings to capture group conversations and actions to provide robust evidence for the findings of this study. Third, our method of clustering group action trajectory patterns using the *KmL* clustering together with a *Jac* coefficient showed promising evidences to understand students' CPS process. However, due to the small sample size, this may need to be further explored at a larger scale. We are currently employing integrated analytical methods to better understand CPS process using such as mixture latent growth curve model to compare the cluster memberships with the results from *KmL*, and multilevel modeling to examine the relative influence of teacher (i.e. two teachers in the middle school) on the action similarity trajectories of the groups.

6. CONCLUSION

This study used a student's daily tool use action sequence generated in a serious game, *Alien Rescue*, to investigate the students' CPS process. We applied a similarity coefficient, *Jac*, to identify a group action similarity trajectory. The *KmL* clustering analysis discovered unique clusters of groups with similar group action trajectories, the membership of which further provided how CPS traits can be related to their learning performance. Each cluster's characteristics shed light on deriving design considerations to promote students' positive collaboration experience during CPS activities within serious games, and to engage teachers in facilitating students' effective CPS process. Lastly, the advantages and limitations of the methods employed in this study point toward the need for continued research on exploring potential analytical methods and scaling up the sample size to include more diverse population.

ABSTRACT

Misconceptions have been an important area of study in STEM education towards improving our understanding of learners' construction of knowledge. The advent of large-scale tutoring systems has given rise to an abundance of data in the form of learner question-answer logs in which signatures of misconceptions can be mined. In this work, we explore the extent to which collected expert misconception diagnoses can be generalized to held-out questions to add misconception semantics. We attempt this generalization by way of a question-answer neural embedding trained on chronological sequences of learner answers. As part of our study, we collect natural language misconception diagnoses from math educators for a sampling of student answers to questions within four topics on Khan Academy. Drawing inspiration from machine translation, we use a multinomial logistic regression model to explore how well the expert misconception semantics, in the form of bag-of-words vectors, can be mapped onto the learned embedding space and interpolated. We evaluate the ability of the space to generalize expert diagnoses using three levels of cross-fold validation in which we measure the recall of predicted natural language diagnoses across rater, topics, and questions. We find that the embedding provides generalization performance substantially beyond baseline approaches.

1. INTRODUCTION

The notion of mapping out abstract spaces of student learning and development has been around for ages, with Zone of Proximal Development [23] serving as a canonical example of defining the area of topics a student could learn with help from peers and the topics beyond. Work in Educational Data Mining has explored mapping out learning spaces taking the form of tree structures [4] or concept nodes in a directed graph [11], often used to represent prerequisite relationships. Other work has mapped out progress points within a course and their relationship to classical psychometric measures of

ability [1]. In this work, we build on the idea of conceiving a space of learning as an embedding, or set of continuous vectors, with parts of the space indicative of different states of understanding and misconception [14]. We learn this embedding from sequences of millions of answers to exercises from a popular STEM tutoring system, then recruit qualified experts to diagnose a sampling of common wrong answers, providing natural language semantics to associate with question answers at their respective locations in the embedding. To test if the embedding generalizes these short form diagnoses, we use linear interpolation of the learned vector space to predict the words used in held-out diagnoses, holding out by expert, problem type, and question in cross-validation experiments. Successful predictive generalization in this task has implications for surfacing automatically generated misconception hypotheses to both teachers and computer tutors.

2. RELATED WORK

The theory of mathematical misconceptions described by Piaget [16], and considered by Smith, diSessa, and Roschelle [19] is one of continually developing partial understandings. Analysis of learner responses, rather than only correctness, may reveal aspects of their understandings. In the age of big data and computation, several modern approaches have brought different perspectives to the analysis of misconceptions. Feldman et al. [5] generated plausible production rules that could have produced the common wrong answers observed in student responses to addition questions in 11 elementary schools. In the vein of KC model or Q-matrix improvement [22], Liu, Patel, & Koedinger [6] explored adding KCs symbolizing buggy production rules to problem steps whose correct answer could be arrived at in spite of applying the buggy production. They found that the inclusion of this item-level misconception tagging improved the overall fit of their AFM model and the validity of the learned individual student parameters. Most complimentary to our work is the work of Michalenko, Lan, & Baraniuk [8], who did not study misconceptions in common wrong answers, but rather misconceptions found in the text of long open response text, using skip-grams and other embedding methods. Their approach is complementary to ours in that it cannot be applied to short, numeric answers in isolation. Inversely, our approach, which extends the embedding context across questions, is driven by questions that generate common wrong answers across students, which would exclude direct applicability to long answer response text.

^{*}At Khan Academy 2016-2017

2.1 Buggy Rules

In the cognitive theories underlying the design of intelligent tutoring systems [2], there are rules that produce correct and consistent answers, and efforts have been made towards cataloging collections of buggy rules that could instead produce incorrect answers. These buggy rules could represent misconceptions that students often have during the learning process [3]. This large collection of buggy rules is often referred to as a bug catalog [20]. As a student moves through a problem set, the bug catalog enables tutoring systems to tag, track, and respond to a path of answers the student provides.

Past research efforts to classify these buggy rules also include the manual labeling of misconceptions by experts [7], the exploration of cluster relationships between the wrong answers [15], and approaches that take into account the frequency of student misconceptions [21]. These efforts lay the foundation for automated approaches which utilize these buggy rules to generate targeted guidance messages specific to each incorrect answer [18].

2.2 Use of Skip-grams

Skip-gram models were originally applied to the embedding of words based on a large corpus of text (e.g. Wikipedia or a large archive of news articles). Once trained, the representational (hidden) layer of these models was shown to encode distributed concepts in the form of syntactic (e.g., bee is to bees as goose is to geese) as well as semantic relationships (e.g., Einstein is to scientist as Picasso is to painter) [10]. While conventionally applied to language in its debut, skip-grams have been applied to non-linguistic data from education. University courses were embedded from sequences of enrollments [13] to find course similarities outside of what could be inferred from catalog descriptions. Questions within the ASSISTments tutoring platform were embedded based on sequences in which problems were answered in order to predict the skill of untagged questions [12]. Skip-grams and other embedding models have been applied to standard natural language in educational contexts, such as the learning of vector representations of open response text and correlating vector representations with the presence or absence of hand coded misconceptions[8].

3. TUTOR DATA SET

Our dataset of anonymized student answer logs comes from Khan Academy, an online STEM tutoring platform. As described in our previous work [14], Khan Academy categorizes student responses by *exercise*, a broad skill similar to those seen in ASSISTments Skill Builder sets; by *problem type*, a problem template; and finally by *seed*, one of two hundred values per problem type which uniquely identifies a template instantiation. Each log entry also contains an anonymous user ID and timestamp, which we use to group and chronologically sort student answers for model training.

We used the same exercise selection process as in [14] to narrow our focus to exercises with sufficient data and concerning topics that would likely surface interesting misconceptions for educators to analyze and describe. This involved consulting a subject matter expert in mathematical education [17] and verifying the correctness of the log entries by forming a sample set of questions and manually accessing their respective web pages on Khan Academy. At the conclusion of this

filtering process, we identified four suitable exercises to use in our experiments:

1. “Surface Areas” (SA)
2. “Slope from an equation in slope intercept form” (SESI)
3. “Area of quadrilaterals and polygons” (AQP)
4. “Adding and subtracting fractions” (ASF)

Table 1 shows statistics for each exercise.

	SA	SESI	AQP	ASF
Problem Types	6	2	2	7
Seeds	38	20	50	40
Students	105,659	33,603	58,239	179,263
Unique Incorrect Answers	55,126	6,912	17,998	46,516
Total Incorrect Answers	619,045	112,390	298,356	873,916

Table 1: Descriptive statistics of exercises used to train the skip-gram models.

A second dataset was collected as part of this study, which consisted of natural language diagnoses of common wrong answers from our chosen exercises. These diagnoses were written by mathematics educators, with each diagnosis explaining the misconception that was potentially responsible for the incorrect answer. We collected misconception diagnosis labels using an online survey platform.¹ We describe the collection of these data in Section 4.2.

4. METHODOLOGY

In this section, we describe the techniques employed to complete three primary methodological tasks:

1. Generate learned question answer embeddings from student answer logs
2. Generate bag-of-words representations of the semantic data contained in educator diagnoses of the misconceptions associated with the incorrect student answers from (1.)
3. Compute a model that generalizes semantic diagnoses of wrong answers based on regression from the continuous vectors of (1.) to the semantic representations from (2.)

Figure 1 depicts the full data processing and machine learning pipeline that we implemented to complete these tasks, using both the answer event logs and the misconception diagnoses as inputs and outputting natural language diagnoses for held-out question answers.

4.1 Embedding Student Answers

As described in Section 2, machine learning models originally intended to model natural language have recently been applied to a number of other domains, including education. Motivated by the success of these efforts, we used a skip-gram neural network model to learn representations of student answers. A representation in our setting, or *embedding*, is a vector in a high-dimensional space that is learned by a skip-gram model. We use the same strategy as in [14] to encode each student answer in a token containing its *seed* and the

¹<https://qualtrics.com>

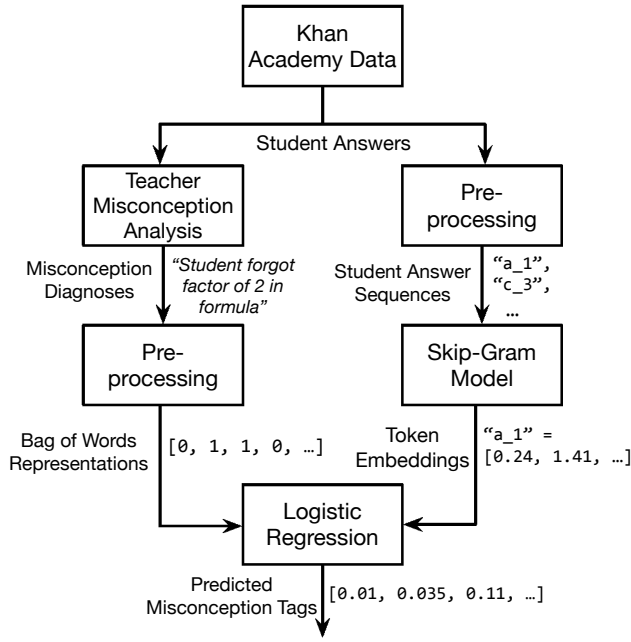

Figure 1: The pipeline used to model student answers, teacher diagnoses, and their correlation.

frequency rank of the student’s response within that seed. For example, if a student were to answer a question generated from seed x01b with the most frequently occurring incorrect answer to that question, their answer would be represented by the token x01b_1.

A skip-gram model is a two-layer neural network (one hidden layer) that analyzes a corpus of token sequences to learn continuous vector representations for each of these tokens. Vectors are trained with the goal of predicting the context of each token. For example, x01b_2 would have s03c_4 in its context if students often provide incorrect responses to those questions in succession. The loss function (Eq. 1) for the training process, described in [10], seeks to optimize the log-likelihood of the tokens in context given a specific input token. S represents the set of input sequences for the model, each corresponding to a student’s sequence of responses to a given exercise. c represents the window size, a hyperparameter of the model that specifies the width of a token’s context when learning its representation, and T represents the number of tokens in sequence s .

$$C = - \sum_{s \in S} \frac{1}{T} \sum_{t=1}^T \sum_{\substack{-c \leq j \leq c \\ j \neq 0}} \log P(w_{t+j} | w_t) \quad (1)$$

We use the negative sampling variant for training the skip-grams as introduced in [10], which replaces the final term of the form $\log P(w_O | w_I)$ in Equation 1 with

$$\log \sigma \left(v_{w_O}^T v_{w_I} \right) + \sum_{i=1}^k \mathbb{E}_{w_i \sim P_n(w)} \left[\log \sigma \left(-v_{w_i}^T v_{w_I} \right) \right] \quad (2)$$

Above, σ represents the sigmoid function. Roughly, this formulation seeks to include the weights of k randomly chosen negative samples, i.e., tokens w_i that do *not* occur within

the context of the target token w_O , in the backpropagation process. Unlike the original hierarchical softmax formulation, negative sampling has the advantage of only adjusting pairs of weights in the underlying network during backpropagation.

4.2 Collecting Teacher Diagnoses

We collected expert-generated semantic misconception diagnosis data through a questionnaire designed and run on the Qualtrics platform. Qualtrics recruited survey participants and compensated them on our behalf at a rate of \$30 per participant. We had Qualtrics recruit participants who:

- Are working as a mathematics educator for students who are in grades 5–12 or undergraduates
- Have at least two years of prior teaching experience

The number of problem types and seeds within each exercise included in the survey is shown in Table 2. For each seed, we formed a batch of the five most frequently submitted incorrect answers to present to survey participants.

Exercise	# Prob. Types	# Seeds
Slope from an Equation in Slope Intercept Form	2	17
Adding and Subtracting Fractions	5	18
Surface Areas	6	36
Area of Quadrilaterals and Polygons	2	18

Table 2: Wrong answer exercises, problem types, and seeds for which expert diagnoses were sought

Each survey participant was provided with initial instructions, excerpted in Figure 2. Next, they were shown three randomly selected answer batches. For each batch, the survey respondent was presented with a screenshot of the original question as it appeared on Khan Academy, the text of the five incorrect student answers, and text boxes to write a brief misconception diagnosis for each answer. An example Khan Academy question and the associated diagnoses we collected are shown in Figure 3.

Respond with a general label-phrase that describes the most likely error or misconception related to the incorrect answer.

- Avoid references to specifics of the question (e.g., do not say “additive inverse is 4, not -4 ”).
- Your label or phrase should be general enough such that it could potentially be applied to other incorrect answers. Therefore, you may duplicate labels and phrases as you see appropriate.
- Avoid abbreviations (e.g., use “y intercept” instead of “yint”).

Example Responses

Question: Solve $3x - 4 = 20$

Student Answer: $5 \frac{1}{3}$

Example Label-Phrase: opposite of additive inverse

Figure 2: An excerpt of the instructions presented to survey participants providing expert diagnoses

Alternatively, we could have asked experts to create misconception labels out of terms drawn from a fixed taxonomy,

$$-\frac{1}{4} - \left(-\frac{3}{5}\right) = \square$$

Answer	Misconception Diagnosis
17/20	Added 5 + 12 instead of 5 − 12.
−17/20	Added 5 + 12 instead of 5 − 12. And used incorrect sign.
−7/20	Has incorrect sign. Should be +.
2/5	Did not use common denominator.

Figure 3: A sample Khan Academy question and corresponding misconception labels

rather than to compose these labels from scratch and without explicit guidance. However, the terms in this taxonomy would inevitably reflect our own biases and assumptions and may prevent experts from accurately describing their observations. Instead, we allowed a broad vernacular, but also asked experts to review their labels at the end of the survey to encourage them to be consistent in their language.

We found that the quality of survey responses varied dramatically within our dataset and developed a procedure to identify and retain only misconception labels that were suitable for further analysis. We manually excluded all responses where an attempt at a label was clearly not present, such as “idk.” Next, we retained diagnoses only from experts who wrote labels with an average length of 20 characters or more. This process left us with 570 unique diagnoses covering 14 of the 15 problem types and 64 of the 89 seeds.

4.3 Processing Teacher Diagnoses

After collecting expert misconception diagnoses through the survey platform, we performed data pre-processing to eventually represent each label in bag-of-words form. Many diagnoses contained references to specific numbers found in the instantiation of the question. We chose not to give every numerical quantity its own token but rather to replace each contiguous mathematical expression with the token `numN`, representing the N^{th} contiguous expression appearing in the diagnoses for each seed. Numbers used to describe general misconception rules, e.g. the factor of $1/2$ used in computing the area of a triangle, were hand-identified and allowed to be represented in original form. This helps to prevent our models from incorrectly identifying correlations that are coincidental (two question instances happen to use the same random quantity) rather than structural.

Next, we stripped punctuation, removed stopwords, and performed word stemming. Finally, we manually removed some of the most common tokens that we deemed uninformative and which could have resulted in trivially easy prediction due to their frequency, such as `student`, `tried`, and `used`. Each processed expert diagnosis is represented as a bag-of-words vector, where an element of the vector indicates the number of occurrences of a term from a global vocabulary. Where we had multiple expert labels available for a single incorrect student answer, we concatenated the two labels and constructed a bag-of-words representation of the result.

		Crossfold Type		
		Evaluator	Prob Type	Seed
Training	Folds	19	14	64
	Data Points	302	296	314
	Evaluators	18	19	19
	Exercises	4	4	4
	Prob Types	14	13	14
	Seeds	61	59	63
Test	Data Points	17	24	5
	Evaluators	1	3	1
	Exercises	2	1	1
	Prob Types	2	1	1
	Seeds	3	5	1

Table 3: Statistics for different cross validation schemes. Entries are rounded averages across folds.

4.4 Mapping Answer Vectors to Diagnoses

With both embeddings of student responses and expert-generated diagnoses in hand, we could explore the extent to which the continuous vector representation of an incorrect answer is related to a semantic description of the misconception underlying that answer. We trained a multinomial logistic regression model to calibrate this correspondence that uses a vector embedding of an incorrect student answer to predict the words in the expert’s diagnosis of that answer. The regression takes as input an m -vector representing a student answer, where m is the dimensionality of the skip-gram embedding space (a hyperparameter of the model). The model produces as output an n -vector, where n is the size of the teacher misconception diagnosis vocabulary. Because of the regression’s use of softmax, this n -vector forms a probability distribution across all terms used in the teacher diagnoses. The i^{th} element of the vector expresses the predicted probability that the i^{th} term of the diagnosis vocabulary applies to the student answer.

5. RESULTS

Here, we describe our results and methodology for evaluating the representations produced by a skip-gram model by using logistic regression and the expert-generated misconception diagnoses. We performed a search over the hyperparameters of the skip-gram algorithm and then compared the predictions generated by our machine learning pipeline to two baselines.

5.1 Skip-Gram Model Evaluation

Recall from Figure 1 that we use logistic regression to train a model identifying correlations between embeddings of student answers and semantic explanations of the underlying misconceptions responsible for incorrect answers. The model surfaces correlations by taking a vector representation as input and producing a probability distribution over the vocabulary of terms used by educators in their misconception diagnoses as output.

Using the semantic data collected from educators as ground truth, we evaluated the insights generated through logistic regression when using vectors produced by different skip-gram models as input. We performed a standard leave-one-out cross-validation (CV) procedure on the educator data. We then evaluated the quality of a model’s predicted misconception tags for student answers in the remaining fold using recall at N , where the value of N for each prediction

is equal to the number of terms used in the original expert label for the relevant incorrect answer. This is defined as:

$$R = \frac{|\hat{T}_N \cap T|}{|T|} \quad (3)$$

where T is the set of terms contained in an educator’s misconception diagnosis for an answer, \hat{T}_N is the set of terms corresponding to the N largest entries in the probability distribution produced by the logistic regression when given an embedding of the answer as input, and $N = |T|$.

We performed three leave-one-out cross-validations using each of the following to determine the fold segmentation:

1. *Evaluator*: The ID of the educator who produced the misconception diagnosis.
2. *Problem Type*: The ID of the template used to generate a question.
3. *Seed*: The unique identifier of an instantiated question.

Descriptive statistics concerning the train and test splits for each scheme are summarized in Table 3.

5.2 Results of Hyperparameter Search

We trained over 750 skip-gram models using different combinations of hyperparameters and then ran each model through the cross-validation procedure described above. The hyperparameters we varied were:

1. *Vector Size*: The number of elements in the vector representations learned by the skip-gram model
2. *Window Size*: The width of each token’s context, i.e., the number of surrounding tokens to consider in the loss function defined in Equation 1.
3. *Min Count*: The minimum number of times a token occurs in the training set to be included in the model.
4. *Training Epochs*

Figure 4: Distribution of average recall under the different cross-validation schemes.

Figure 4 shows the distribution of recall results achieved by all the models under each scheme. We also examined the distribution of hyperparameters among the ten models that achieved the highest average recall at N under each cross-validation type. We found that this metric was not sensitive to the hyperparameter values among the top ten models for all CV types. Within each CV type, all models produced scores within $0.0x$ of one another. Table 4 shows the

hyperparameters that produced the best performing models, measured by average recall, for all CV types.

	Evaluator	Problem Type	Seed
Vector Size	60	100	100
Window Size	15	40	8
Min Count	10	15	5
Training Epochs	20	20	20

Table 4: The best skip-gram hyperparameter combinations under each cross validation scheme.

5.3 Diagnosis Generalization by Best Models

We compared the recall achieved by predicting the words in the diagnoses using the best skip-gram embeddings and logistic regression to the recall achieved by two baseline prediction schemes. For each incorrect student answer, all of the methods predict N terms, where N is the number of terms contained in the original expert diagnosis of the underlying misconception for that answer. This ensures we can fairly measure each prediction scheme by recall at N . The two baselines were:

1. *Random*: Generate a random sample of N terms from the vocabulary formed by the expert misconception diagnoses in the training set.
2. *Frequency*: Predict the N terms that appear most frequently in the diagnoses from the training set.

Figure 5: Average recall achieved by different prediction schemes for each cross-validation type.

The average recall at N achieved by the predictions generated through each baseline scheme, as well as that of our own approach, is shown in Figure 5. As expected, a frequency-based approach outperforms a random approach in all three cross-validation types. In addition, the embedding-based approach significantly outperforms the frequency-based approach in all three cases by nearly 100%. The results show that between 18% and 27% of words in held-out diagnoses were recovered. This improvement over baseline suggests a moderate correspondence between the regularities learned in the embedding and semantics used to describe misconceptions.

Recall increased with the size of the training set, with *Seed* having the largest training set and *Evaluator* having the smallest. Other factors may also contribute to these results. First, we chose Khan Academy exercises spanning a diverse selection of mathematical concepts, and the diagnoses for

misconceptions that arise in one domain (e.g., fractions) may use very different diagnosis terms than the terms used for misconceptions in another domain (e.g., surface area). Therefore, there are likely cases where the training set doesn't contain the proper terms to express the misconception diagnoses in the test set. Moreover, different educators used different taxonomies and terms when constructing their misconception diagnoses, which means a model may not be able to accurately predict the diagnoses provided by an educator that isn't well represented in the training data set, which appears to be the situation that arises in *Evaluator* cross-validation.

6. DISCUSSION

Should the 27% recall that we achieved in predicting the terms of held out misconception diagnoses be considered a good score? There are not prior results in this particular area with which to compare to a state of the art. However, this technique of linearly translating from one space (answer embedding) to another (diagnosis bag-of-words) is akin to machine translation from one language's embedding to another. Looking at the accuracy reported in the original linear machine translation paper [9], a translation accuracy of 10% was achieved between English and Vietnamese and 24% translated the other way. Therefore, we could consider 27% a comparable score to past NLP translation benchmarks and a performance level that may produce diagnoses that expert teachers could consider and potentially act on.

A limitation of our approach was that, as discussed in Section 4.2, our survey allowed experts to write open-ended misconception diagnoses which resulted in low frequency of some words and thus a more challenging downstream prediction task. A future study could restrict the terms available for use in expert labels or have them simultaneously negotiate a shared taxonomy. Finally, the student response sequences used as input for the skip-gram models were partitioned by Khan Academy exercise due to us wanting to focus on a limited number of topic areas. This may have lead to missing misconception signatures that manifest or generalize across exercises.

7. ACKNOWLEDGEMENTS

We thank Khan Academy for sharing anonymized exercise data. This work was supported, in part, by a grant from the National Science Foundation (#1547055).

Active Learning of Strict Partial Orders: A Case Study on Concept Prerequisite Relations

ABSTRACT

Strict partial order is a mathematical structure commonly seen in relational data. One obstacle to extracting such type of relations at scale is the lack of large scale labels for building effective data-driven solutions. We develop an active learning framework for mining such relations subject to a strict order. Our approach incorporates relational reasoning not only in finding new unlabeled pairs whose labels can be deduced from an existing label set, but also in devising new query strategies that consider the relational structure of labels. Our experiments on concept prerequisite relations show our proposed framework can substantially improve the classification performance with the same query budget compared to other baseline approaches.

1. INTRODUCTION

Pool-based active learning is a learning framework where the learning algorithm is allowed to access a set of unlabeled examples and ask for the labels of any of these examples [3]. Its goal is to learn a good classifier with significantly fewer labels by actively directing the queries to the most “valuable” examples. In a typical setup of active learning, the label dependency among labeled or unlabeled examples is not considered. But data and knowledge in the real world are often embodied with prior relational structures. Taking into consideration those structures in building machine learning solutions can be necessary and crucial. The goal of this paper is to investigate the query strategies in active learning of a strict partial order, namely, when the ground-truth labels of examples constitute an irreflexive and transitive relation. In this paper, we develop efficient and effective algorithms extending popular query strategies used in active learning to work with such relational data. We study the following problem in the active learning context:

Problem. Given a finite set V , a strict order on V is a type of irreflexive and transitive (pairwise) relation. Such a strict order is represented by a subset $G \subseteq V \times V$. Given an unknown strict order G , an oracle W that returns $W(u, v) =$

$-1 + 2 \cdot \mathbf{1}[(u, v) \in G] \in \{-1, 1\}$, and a feature extractor $\mathcal{F} : V \times V \mapsto \mathbb{R}^d$, find $h : \mathbb{R}^d \mapsto \{-1, 1\}$ from a hypothesis class \mathcal{H} that predicts whether or not $(u, v) \in G$ for each pair $(u, v) \in V \times V$ and $u \neq v$ (using $h(\mathcal{F}(u, v))$) by querying W a finite number of (u, v) pairs from $V \times V$.

Our main focus is to develop reasonable query strategies in active learning of a strict order exploiting both the knowledge from (non-consistent) classifiers trained on a limited number of labeled examples and the deductive structures among pairwise relations. Our work also has a particular focus on *partial orders*. If the strict order is total, a large school called “learning to rank” has studied this topic [10], some of which are under the active learning setting [4]. Learning to rank relies on binary classifiers or probabilistic models that are consistent with the rule of a total order. Such approaches are however limited in a sense to principally modeling a partial order: a classifier consistent with a total order will always have a non-zero lower bound of error rate, if the ground-truth is a partial order but not a total order.

In our active learning problem, incorporating the deductive relations of a strict order in soliciting examples to be labeled is non-trivial and important. The challenges motivating us to pursue this direction can be explained in three folds: First, any example whose label can be deterministically reasoned from a labeled set by using the properties of strict orders does not need further manual labeling or statistical prediction. Second, probabilistic inference of labels based on the independence hypothesis, as is done in the conventional classifier training, is *not* proper any more because the deductive relations make the labels of examples dependent on each other. Third, in order to quantify how valuable an example is for querying, one has to combine uncertainty and logic to build proper representations. Sound and efficient heuristics with empirical success are to be explored.

One related active learning work that deals with a similar setting to ours is [13], whereas equivalence relations are considered instead. Particularly, they made several crude approximations in order to expedite the expected error calculation to a computational tractable level. We approach the design of query strategies from a different perspective while keeping efficiency as one of our central concerns.

To empirically study the proposed active learning algorithm, we apply it to *concept prerequisite learning problem* [15, 8], where the goal is to predict whether a concept A is a pre-

Roger Nkambou (eds.) 2019, pp. 348 - 353

requisite of a concept B given the pair (A, B) . Although there have been some research efforts towards learning prerequisites [16, 15, 8, 17], the mathematical nature of the prerequisite relation as strict partial orders has not been investigated. In addition, one obstacle for effective learning-based solutions to this problem is the lack of large scale prerequisite labels. Liang et al. [9] applied standard active learning to this problem without utilizing relation properties of prerequisites. Active learning methods tailored for strict partial orders provide a good opportunity to tackle the current challenges of concept prerequisite learning.

Our main contributions are summarized as follows: First, we propose a new efficient reasoning module for monotonically calculating the deductive closure under the assumption of a strict order. This computational module can be useful for general AI solutions that need fast reasoning in regard to strict orders. Second, we apply our reasoning module to extend two popular active learning approaches to handle relational data and empirically achieve substantial improvements. This is the first attempt to design active learning query strategies tailored for strict partial orders. Third, under the proposed framework, we solve the problem of concept prerequisite learning and our approach appears to be successful on data from four educational domains, whereas previous work have not exploited the relational structure of prerequisites as strict partial orders in a principled way.

2. REASONING OF A STRICT ORDER

2.1 Preliminary

DEFINITION 1 (STRICT ORDER). Given a finite set V , a subset G of $V \times V$ is called a strict order if and only if it satisfies the two conditions: (i) if $(a, b) \in G$ and $(b, c) \in G$, then $(a, c) \in G$; (ii) if $(a, b) \in G$, then $(b, a) \notin G$.

DEFINITION 2 (G-ORACLE). For two subsets $G, H \subseteq V \times V$, a function denoted as $W_H(\cdot, \cdot) : H \mapsto \{-1, 1\}$ is called a G -oracle on H iff for any $(u, v) \in H$, $W_H(u, v) = -1 + 2 \cdot \mathbf{1}[(u, v) \in G]$.

The G -oracle returns a label denoting whether a pair belongs to G .

DEFINITION 3 (COMPLETENESS OF AN ORACLE). A G -oracle of strict order W_H is called complete if and only if H satisfies: for any $a, b, c \in V$, (i) if $(a, b) \in H \cap G$, $(b, c) \in H \cap G$, then $(a, c) \in H \cap G$; (ii) if $(a, b) \in H \cap G$, $(a, c) \in H \cap G^c$, then $(b, c) \in H \cap G^c$; (iii) if $(b, c) \in H \cap G$, $(a, c) \in H \cap G^c$, then $(a, b) \in H \cap G^c$; (iv) if $(a, b) \in H \cap G$, then $(b, a) \in H \cap G^c$, where G^c is the complement of G . W_H is called complete if it is consistent under transitivity when restricted on pairs from H .

DEFINITION 4 (CLOSURE). Given a strict order G , for any $H \subseteq V \times V$, its closure is defined to be the smallest set \bar{H} such that $H \subseteq \bar{H}$ and the G -oracle $W_{\bar{H}}$ is complete.

DEFINITION 5 (DESCENDANT AND ANCESTOR). Given a strict order G of V and $a \in V$, its ancestor subject to G is $A_a^G := \{b \mid (b, a) \in G\}$ and its descendant is $D_a^G := \{b \mid (a, b) \in G\}$.

2.2 Reasoning Module for Closure Calculation

With the definitions in the previous section, this section proposes a reasoning module that is designed to monotonically calculate the deductive closure for strict orders. Remark

that a key difference between the traditional transitive closure and our definition of closure (Definition 3&4) is that the former only focuses on G but the latter requires calculation for both G and G^c . In the context of machine learning, relations in G and G^c correspond to positive examples and negative examples, respectively. Since both of these examples are crucial for training classifiers, existing algorithms for calculating transitive closure such as the Warshall algorithm are not applicable. Thus we propose the following theorem for monotonically computing the closure. Please refer to supplemental material for the proofs.

THEOREM 1. Let G be a strict order of V and W_H a complete G -oracle on $H \subseteq V \times V$. For any pair $(a, b) \in V \times V$, define the notation $C_{(a,b)}$ by

(i) If $(a, b) \in H$, $C_{(a,b)} := H$.

(ii) If $(a, b) \in G^c \cap H^c$, $C_{(a,b)} := H \cup N'_{(a,b)}$ where

$$N'_{(a,b)} := \{(d, c) \mid c \in A_a^{G \cap H} \cup \{b\}, d \in D_b^{G \cap H} \cup \{a\}\},$$

and particularly $N'_{(a,b)} \subseteq G^c$.

(iii) If $(a, b) \in G \cap H^c$, $C_{(a,b)} := H \cup N_{(a,b)} \cup R_{(a,b)} \cup S_{(a,b)} \cup T_{(a,b)} \cup O_{(a,b)}$, where

$$N_{(a,b)} := \{(c, d) \mid c \in A_a^{G \cap H} \cup \{a\}, d \in D_b^{G \cap H} \cup \{b\}\},$$

$$R_{(a,b)} := \{(d, c) \mid (c, d) \in N_{(a,b)}\},$$

$$S_{(a,b)} := \{(d, e) \mid c \in A_a^{G \cap H} \cup \{a\}, d \in D_b^{G \cap H} \cup \{b\}, (c, e) \in G^c \cap H\},$$

$$T_{(a,b)} := \{(e, c) \mid c \in A_a^{G \cap H} \cup \{a\}, d \in D_b^{G \cap H} \cup \{b\}, (e, d) \in G^c \cap H\},$$

$$O_{(a,b)} := \bigcup_{(c,d) \in S_{(a,b)} \cup T_{(a,b)}} N''_{(c,d)},$$

$$N''_{(c,d)} := \{(f, e) \mid e \in A_d^{G \cap (H \cup N_{(a,b)})} \cup \{d\}, f \in D_c^{G \cap (H \cup N_{(a,b)})} \cup \{c\}\}.$$

In particular, $N_{(a,b)} \subseteq G$ and $R_{(a,b)} \cup S_{(a,b)} \cup T_{(a,b)} \cup O_{(a,b)} \subseteq G^c$.

For any pair $(x, y) \in V \times V$, the closure of $H' = H \cup \{(x, y)\}$ is $C_{(x,y)}$.

Figure 1 provides an informal explanation of each necessary condition (except for $R_{(a,b)}$) mentioned in the theorem. If (a, b) is a positive example, i.e. $(a, b) \in G$, then (i) $N_{(a,b)}$ is a set of inferred positive examples by transitivity; (ii) $R_{(a,b)}$ is a set of inferred negative examples by irreflexivity; (iii) $S_{(a,b)}$ and $T_{(a,b)}$ are sets of inferred negative examples by transitivity; (iv) $O_{(a,b)}$ is a set of negative examples inferred from $S_{(a,b)}$ and $T_{(a,b)}$. If (a, b) is a negative example, i.e. $(a, b) \in G^c$, then $N'_{(a,b)}$ is a set of negative examples inferred by transitivity.

3. POOL-BASED ACTIVE LEARNING

The pool-based sampling [7] is a typical active learning scenario in which one maintains a labeled set \mathcal{D}_l and an unlabeled set \mathcal{D}_u . In particular, we let $\mathcal{D}_u \cup \mathcal{D}_l = \mathcal{D} = \{1, \dots, n\}$ and $\mathcal{D}_u \cap \mathcal{D}_l = \emptyset$. For $i \in \{1, \dots, n\}$, we use $\mathbf{x}_i \in \mathbb{R}^d$ to denote a feature vector representing the i -th instance, and $y_i \in \{-1, +1\}$ to denote its groundtruth class label. At each round, one or more instances are selected from \mathcal{D}_u whose label(s) are then requested, and the labeled instance(s) are

Figure 1: Following the notations in Theorem 1: (a) Black lines are pairs in H , solid lines are pairs in G , and dashed lines are pairs in G^c . The pair (a, b) in the cyan color is the pair to be labeled or deduced. (b) If $(a, b) \in G$, $\{(a, b), (e, f), (a, f), (e, b)\} \subseteq N_{(a, b)}$. (c) If $(a, b) \in G$, $\{(h, e), (h, a)\} \subseteq T_{(a, b)}$ and $\{(b, g), (f, g)\} \subseteq S_{(a, b)}$. (d) If $(a, b) \in G^c$, $\{(a, b), (a, d), (c, b), (c, d)\} \subseteq N'_{(a, b)}$. Likewise, if $\exists (x, y) \in G$, s.t. $(a, b) \in S_{(x, y)} \cup T_{(x, y)}$, $\{(a, b), (a, d), (c, b)\} \subseteq O_{(x, y)}$.

then moved to \mathcal{D}_l . Typically instances are queried in a prioritized way such that one can obtain good classifiers trained with a substantially smaller set \mathcal{D}_l . We focus on the pool-based sampling setting where queries are selected in serial, i.e., one at a time.

3.1 Query Strategies

The key component of active learning is the design of an effective criterion for selecting the most “valuable” instance to query, which is often referred to as *query strategy*. We use s^* to refer to the selected instance by the strategy. In general, different strategies follow a greedy framework:

$$s^* = \underset{s \in \mathcal{D}_u}{\operatorname{argmax}} \min_{y \in \{-1, 1\}} f(s; y, \mathcal{D}_l), \quad (1)$$

where $f(s; y, \mathcal{D}_l) \in \mathbb{R}$ is a scoring function to measure the risks of choosing y as the label for $\mathbf{x}_s \in \mathcal{D}_u$ given an existing labeled set \mathcal{D}_l .

We investigate two commonly used query strategies: uncertainty sampling [6] and query-by-committee [14]. We show that under the binary classification setting, they can all be reformulated as Eq. (1).

Uncertainty Sampling selects the instance which it is least certain how to label. We choose to study one popular uncertainty-based sampling variant, the *least confident*. Subject to Eq. (1), the resulting approach is to let

$$f(s; y, \mathcal{D}_l) = 1 - P_{\Delta(\mathcal{D}_l)}(y_s = y | \mathbf{x}_s), \quad (2)$$

where $P_{\Delta(\mathcal{D}_l)}(y_s = y | \mathbf{x}_s)$ is a conditional probability which is estimated from a probabilistic classification model Δ trained on $\{(\mathbf{x}_i, y_i) \mid \forall i \in \mathcal{D}_l\}$.

Query-By-Committee maintains a committee of models trained on labeled data, $\mathcal{C}(\mathcal{D}_l) = \{g^{(1)}, \dots, g^{(C)}\}$. It aims to reduce the size of version space. Specifically, it selects the unlabeled instance about which committee members disagree the most based on their predictions. Subject to Eq. (1), the resulting approach is to let

$$f(s; y, \mathcal{D}_l) = \sum_{k=1}^C \mathbf{1}[y \neq g^{(k)}(\mathbf{x}_s)], \quad (3)$$

where $g^{(k)}(\mathbf{x}_s) \in \{-1, 1\}$ is the predicted label of \mathbf{x}_s using the classifier $g^{(k)}$.

Our paper will start from generalizing Eq. (1) and show that it is possible to extend the two popular query strategies for considering relational data as a strict order.

4. ACTIVE LEARNING OF A STRICT ORDER

Given G a strict order of V , consider a set of data $\mathcal{D} \subseteq V \times V$, where $(a, a) \notin \mathcal{D}, \forall a \in V$. Similar to the pool-based active learning, one needs to maintain a labeled set \mathcal{D}_l and an unlabeled set \mathcal{D}_u . We require that $\mathcal{D} \subseteq \mathcal{D}_l \cup \mathcal{D}_u$ and $\mathcal{D}_l \cap \mathcal{D}_u = \emptyset$. Given a feature extractor $\mathcal{F}: V \times V \mapsto \mathbb{R}^d$, we can build a vector dataset $\{\mathbf{x}_{(a, b)} = \mathcal{F}(a, b) \in \mathbb{R}^d \mid (a, b) \in \mathcal{D}\}$. Let $y_{(a, b)} = -1 + 2 \cdot \mathbf{1}[(a, b) \in G] \in \{-1, 1\}$ be the ground-truth label for each $(a, b) \in V \times V$. Active learning aims to query Q a subset from \mathcal{D} under limited budget and construct a label set \mathcal{D}_l from Q , in order to train a good classifier h on $\mathcal{D}_l \cap \mathcal{D}$ such that it predicts accurately whether or not an unlabeled pair $(a, b) \in G$ by $h(\mathcal{F}(a, b)) \in \{-1, 1\}$.

Active learning of strict orders differs from the traditional active learning in two unique aspects: (i) By querying the label of a single unlabeled instance, one may obtain a set of labeled examples, with the help of strict orders’ properties; (ii) The relational information of strict orders could also be utilized by query strategies. We will present our efforts towards incorporating the above two aspects into active learning of a strict order.

4.1 Basic Relational Reasoning in Active Learning

A basic extension from standard active learning to one under the strict order setting is to apply relational reasoning when both updating \mathcal{D}_l and predicting labels. Algorithm 1 shows the pseudocode for the pool-based active learning of a strict order. When updating \mathcal{D}_l with a new instance $(a, b) \in \mathcal{D}_u$ whose label $y_{(a, b)}$ is acquired from querying, one first calculates $\overline{\mathcal{D}_l}$, i.e., the closure of $\mathcal{D}_l \cup \{(a, b)\}$, using Theorem 1, and then sets $\mathcal{D}_l := \overline{\mathcal{D}_l}$ and $\mathcal{D}_u := \mathcal{D} \setminus \overline{\mathcal{D}_l}$ respectively. Therefore, it is possible to augment the labeled set \mathcal{D}_l with more than one pair at each stage even though only a single instance is queried. Furthermore, the following corollary shows that given a fixed set of samples to be queried, their querying order does not affect the final labeled set \mathcal{D}_l constructed.

COROLLARY 1.1. *Given a list of pairs Q of size m whose elements are from $V \times V$, let i_1, \dots, i_m and j_1, \dots, j_m be two different permutations of $1, \dots, m$. Let $I_0 = \emptyset$ and $J_0 = \emptyset$, and $I_k = I_{k-1} \cup \{q_{i_k}\}$, $J_k = J_{k-1} \cup \{q_{j_k}\}$ for $k = 1, \dots, m$, where $\bar{\cdot}$ is defined as the closure set under G . We have $I_m = J_m$, which is the closure of $\{q_i \in V \times V \mid i = 1, \dots, m\}$.*

Corollary 1.1 is a straightforward result from the uniqueness of closure, which is also verified by our experiments. The la-

Algorithm 1 Pseudocode for pool-based active learning of a strict order.

Input:
 $\mathcal{D} \subseteq V \times V$ % a data set

Initialize:
 $\mathcal{D}_l \leftarrow \{(a_{s_1}, b_{s_1}), (a_{s_2}, b_{s_2}), \dots, (a_{s_k}, b_{s_k})\}$ % initial labeled set with k seeds
 $\mathcal{D}_l \leftarrow \overline{\mathcal{D}_l}$ % initial closure
 $\mathcal{D}_u \leftarrow \mathcal{D} \setminus \mathcal{D}_l$ % initial unlabeled set

while $\mathcal{D}_u \neq \emptyset$ **do**
 Select (a^*, b^*) from \mathcal{D}_u % according to a query strategy
 Query the label $y_{(a^*, b^*)}$ for the selected instance (a^*, b^*)
 $\mathcal{D}_l \leftarrow \mathcal{D}_l \cup \{(a^*, b^*)\}$
 $\mathcal{D}_u \leftarrow \mathcal{D} \setminus \mathcal{D}_l$
end while

beled set \mathcal{D}_l contains two kinds of pairs based on where their labels come from: The first kind of labels comes directly from queries, and the second kind comes from the relational reasoning as explained by Theorem 1. Such an approach has a clear advantage over standard active learning at the same budget of queries, because labels of part of the test pairs can be inferred deterministically and as a result there will be more labeled data for supervised training. In our setup of active learning, we train classifiers on $\mathcal{D} \cap \mathcal{D}_l$ and use them for predicting the labels of remaining pairs that are not in \mathcal{D}_l .

4.2 Query Strategies with Relational Reasoning

The relational active learning framework as explained in the previous section however does not consider incorporating relational reasoning in its query strategy. We further develop a systematic approach on how to achieve this.

We start from the following formulation: at each stage, one chooses a pair (a^*, b^*) to query based on

$$(a^*, b^*) = \operatorname{argmax}_{(a,b) \in \mathcal{D}_u} \min_{y \in \{-1, 1\}} F(\mathcal{S}(y_{(a,b)} = y), \mathcal{D}_l), \quad (4)$$

$$\mathcal{S}(y_{(a,b)} = y) = (\overline{\mathcal{D}_l \cup \{(a,b)\}} \setminus \mathcal{D}_l) \cap \mathcal{D}. \quad (5)$$

Again, F is the scoring function. $\mathcal{S}(y_{(a,b)} = y)$ is the set of pairs in \mathcal{D} whose labels, originally unknown ($\notin \mathcal{D}_l$), can now be inferred by assuming $y_{(a,b)} = y$ using Theorem 1. For each $(u, v) \in \mathcal{S}(y_{(a,b)} = y)$, its inferred label is denoted as $\hat{y}_{(u,v)}$ in the sequel. One can see that this formulation is a generalization of Eq. (1). We now proceed to develop extensions for the two query strategies to model the dependencies between pairs imposed by the rule of a strict order. Following the same notations as previously described with the only difference that the numbering index is replaced by the pairwise index, we propose two query strategies tailored to strict orders.

Uncertainty Sampling with Reasoning. With relational reasoning, one not only can reduce the uncertainty of the queried pair (a, b) but also may reduce that of other pairs deduced

Table 1: Dataset statistics.

Domain	# Concepts	# Pairs	# Prerequisites
Data Mining	120	826	292
Geometry	89	1681	524
Physics	153	1962	487
Precalculus	224	2060	699

by assuming $y_{(a,b)} = y$. The modified scoring function reads:

$$F(\mathcal{S}(y_{(a,b)} = y), \mathcal{D}_l) = \sum_{(u,v) \in \mathcal{S}(y_{(a,b)} = y)} 1 - P_{\Delta(\mathcal{D}_l \cap \mathcal{D})}(y_{(u,v)} = \hat{y}_{(u,v)} | \mathbf{x}_{(u,v)}). \quad (6)$$

Query-by-Committee with Reasoning. Likewise, one also has the extension for QBC, where $\{g^{(k)}\}_{k=1}^C$ is a committee of classifiers trained on bagging samples of $\mathcal{D}_l \cap \mathcal{D}$,

$$F(\mathcal{S}(y_{(a,b)} = y), \mathcal{D}_l) = \sum_{(u,v) \in \mathcal{S}(y_{(a,b)} = y)} \sum_{k=1}^C \mathbf{1}(\hat{y}_{(u,v)} \neq g^{(k)}(\mathbf{x}_{(u,v)})). \quad (7)$$

5. EXPERIMENTS

For evaluation, we apply the proposed active learning algorithms to *concept prerequisite learning problem* [8]. Given a pair of concepts (A, B) , we predict whether or not A is a prerequisite of B , which is a binary classification problem. Here, cases where B is a prerequisite of A and where no prerequisite relation exists are both considered negative.

5.1 Dataset

We use the Wiki concept map dataset from [17] which is collected from textbooks on different educational domains. Each concept corresponds to an English Wiki article. For each domain, the dataset consists of prerequisite pairs in the concept map. Table 1 summarizes the statistics of the our final processed dataset.

5.2 Features

For each concept pair (A, B) , we calculate two types of features following the popular practice of information retrieval and natural language processing: graph-based features and text-based features. Please refer to Table 2 for detailed description. Note we trained a topic model [1] on the Wiki corpus. We also trained a Word2Vec [12] model on the same corpus with each concept treated as an individual token.

5.3 Experiment Settings

We follow the typical evaluation protocol of pool-based active learning. We first randomly split a dataset into a training set \mathcal{D} and a test set \mathcal{D}_{test} with a ratio of 2:1. Then we randomly select 20 samples from the training set as the initial query set Q and compute its closure \mathcal{D}_l . Meanwhile, we set $\mathcal{D}_u = \mathcal{D} \setminus \mathcal{D}_l$. In each iteration, we pick an unlabeled instance from \mathcal{D}_u to query for its label, update the label set \mathcal{D}_l , and re-train a classification model on the updated $\mathcal{D}_l \cap \mathcal{D}$. The re-trained classification model is then evaluated on \mathcal{D}_{test} . In all experiments, we use a random forests classifier [2] with 200 trees as the classification model. We use Area under the ROC curve (AUC) as the evaluation metric. Taking into account the effects of randomness subject to different initializations, we continue the above experimental process for each method repeatedly with 300 pre-selected distinct random seeds. Their average scores and

Table 2: Feature description. Top: graph-based features. Bottom: text-based features.

Feature	Description
In/Out Degree	The in/out degree of A/B.
Common Neighbors	# common neighbors of A and B.
# Links	# times A/B links to B/A.
Link Proportion	The proportion of pages that link to A/B also link to B/A.
NGD	The Normalized Google Distance between A and B [18].
PMI	The Pointwise Mutual Information relatedness between the incoming links of A and B.
RefD	A metric to measure how differently A and B's related concepts refer to each other [8].
HITS	The difference between A and B's hub/authority scores. [5]
1st Sent	Whether A/B is in the first sentence of B/A.
In Title	Whether A appears in B's title.
Title Jaccard	The Jaccard similarity between A and B's titles.
Length	# words of A/B's content.
Mention	# times A/B are mentioned in the content of B/A.
NP	# noun phrases in A/B's content; # common noun phrases.
Tf-idf Sim	The cosine similarity between Tf-idf vectors for A and B's first paragraphs.
Word2Vec Sim	The cosine similarity between vectors of A and B trained by Word2Vec.
LDA Entropy	The Shannon entropy of the LDA vector of A/B.
LDA Cross Entropy	The cross entropy between the LDA vector of A/B and B/A.

Table 3: Summary of compared query strategies.

Random-R	✓	✗	✗
LC-R, QBC-R	✓	✗	✓
CNT	✓	✓	✗
LC-R+, QBC-R+	✓	✓	✓

confidence intervals ($\alpha = 0.05$) are reported. We compare four query strategies: (i) **Random**: randomly select an instance to query; (ii) **LC**: least confident sampling, a widely used uncertainty sampling variant. We use logistic regression to estimate posterior probabilities; (iii) **QBC**: query-by-committee algorithm. We apply query-by-bagging [11] and use a committee of three decision trees; (iv) **CNT**: a simple baseline query strategy designed to greedily select an instance whose label can potentially infer the most number of unlabeled instances. Following the previous notations, the scoring function for CNT is $F(\mathcal{S}(y_{(a,b)} = y), \mathcal{D}_l) = |S(y_{(a,b)} = y)|$, which is solely based on logical reasoning.

For experiments, we test each query strategy under three settings: (i) Traditional active learning where no relational information is considered. Query strategies under this setting are denoted as Random, LC, and QBC. (ii) Relational active learning where relation reasoning is applied to updating \mathcal{D}_l and predicting labels of \mathcal{D}_{test} . Query strategies under this setting are denoted as Random-R, LC-R, and QBC-R. (iii) Besides being applied to updating \mathcal{D}_l , relational reasoning is also incorporated in the query strategies. Query strategies under this setting are the baseline method CNT and our proposed extensions of LC and QBC for strict partial orders, denoted as LC-R+ and QBC-R+, respectively. Table 3 summarizes the query strategies studied in the experiments.

5.4 Experiment Results

Figure 2 shows the AUC results of different query strategies. For each case, we present the average values and 95% C.I. of repeated 300 trials with different train/test splits. In addition, Figure 3 compares the relations between the number of queries and the number of labeled instances across different query strategies. Note that in the relational active learning setting querying a single unlabeled instance will result in one or more labeled instances. According to Figure 2 and Figure 3, we have the following observations: First, by comparing query strategies under the settings (ii) and (iii) with setting (i), we observe that incorporating relational reasoning into active learning substantially improves the AUC performance of each query strategy. In addition, we find the query order, which is supposed to be different for each strategy, does not affect \mathcal{D}_l at the end when $\mathcal{D} \subseteq \mathcal{D}_l$. Thus, it partly verifies Corollary 1.1. Second, our proposed LC-R+ and QBC-R+ significantly outperform other compared query strategies. Specifically, when comparing them with LC-R and QBC-R, we see that incorporating relational reasoning into directing the queries helps to train a better classifier. Figure 3 shows that LC-R+ and QBC-R+ lead to more labeled instances when using the same amount of queries than that of LC-R and QBC-R. This partly contributes to the performance gain. Third, LC-R+ and QBC-R+ are more effective at both collecting a larger labeled set and training better classifiers than the CNT baseline. In addition, by comparing CNT with LC-R, QBC-R, and Random-R, we observe that a larger size of the labeled set does not always lead to a better performance. Such observations demonstrate the necessity of combining deterministic relational reasoning and probabilistic machine learning in designing query strategies.

In addition to effectiveness, we also conduct empirical studies on the runtime of the reasoning module and include the results in the supplemental material.

6. CONCLUSION

We propose an active learning framework tailored to relational data in the form of strict partial orders. An efficient reasoning module is proposed to extend two commonly used query strategies – uncertainty sampling and query by committee. Experiments on concept prerequisite learning show that incorporating relational reasoning in both selecting valuable examples to label and expanding the training set significantly improves standard active learning approaches. Future work could be to explore the following: (i) apply the reasoning module to extend other query strategies; (ii) active learning of strict partial orders from a noisy oracle.

ABSTRACT

This work aims to characterize students' writing processes using keystroke logs and understand how the extracted characteristics influence the text quality at specific moments of writing. Earlier works have proposed predictive models characterizing students' writing processes and mainly rely on distribution-based measures of pauses obtained from the overall keystroke logs. However, the effect of isolated phases of writing has not been evaluated in these models. Moreover, current theories on writing suggest that the quality of writing depends on when specific writing behaviours are performed. This view is not examined in the keystroke logging analysis literature. Addressing the mentioned challenges, the two contributions of this work are: a) characterizing students' writing processes connected to isolated writing phases and examining their influence on writing quality; and b) temporal analysis of keystrokes and investigating whether the significance of writing characteristics varies as students progress in their writing task. Our results suggest that characterizing students' writing based on isolated writing phases is slightly more predictive of writing quality. Additionally, the effect of several writing characteristics on writing quality changes when considering the time dimension.

Writing process, Keystroke log, XGBoost, SHAP feature importance, Temporal analysis

1. INTRODUCTION

The recognized significance of the writing process has led to the emergence of a wide variety of research exploring the process of students' academic writing. The writing process, broadly including planning, writing and revising phases, is a non-linear process [10]. These phases often occur simultaneously, making it challenging for researchers to examine features related to specific writing phases.

One stream of writing research has focused on analyzing pauses in keystroke logs and associating them with different phases of the writing process [9]. This is often accomplished by exploring the distribution of pauses and then mapping the related parameters to specific writing processes. Although some keystroke log features can be a marker of a high writing quality, there is not always sufficient evidence for their relationship. This may be due to decisions made during data processing and analysis.

Additionally, statistics and features collected by most studies examining the relationship between keystroke logs and the writing process mainly rely on aggregated or distribution-based representations of the overall keystroke logs [9]. Even when the data has been summarized to a high standard, neglecting the time dimension may hide the effect of specific behaviors at particular moments of the writing process. Temporal analysis has been suggested as a better way to uncover the writing process and its related stages [3]. However, there are a few studies that combine writing process and temporal analysis, which mostly focused on think aloud procedures and offline measurements. These have been criticized as being inaccurate representations of the underlying writing process [16].

Therefore, our main aim is to examine students' writing processes and their relationship to writing quality using keystroke logs and temporal analysis. We use an innovative writing technology platform that assists in discriminating between writing phases, mainly planning and writing, by providing separate writing sections to students [17]. The temporal analysis provides insight about how the effect of each of those phases and keystroke log features on students' writing quality may change over time. This can support educators to make judgments regarding students' writing processes and change the ways they teach writing skills.

2. LITERATURE REVIEW

2.1 Writing Research

A common approach of writing research is to consider three phases to describe the writing process: pre-writing, writing, and post-writing [4]. Pre-writing is composed by planning the content of the text to be written. Writing is composing the ideas and transcribing them. Post-writing is revising or reviewing the written text or plan. For simplicity purposes, in our study these phases are referred to as planning, transcribing, and revising, respectively. Efforts in writing research have been made to identify behavioral features that could be an indication of these phases. Early writing research has heavily relied on self-report methods, such as think aloud protocols [3], to examine students' writing process. Over the recent decades, purpose-built software for writing research were developed which collected all information possible during the writing process. Initially these initiatives were restricted to laboratories, but recent advances in software development has now released such software naturalistic settings, allowing for researchers to examine the writing process in real educational environments [17].

2.2 Keystroke Logs in Writing Research

A key research area uses keystroke logging to characterize the writing process. Efforts here have focused on investigating the distributions of various kinds of pauses (e.g., inter-key, intra-word) and their relationship with writing quality. Among the existing studies, [7] found the exponentially modified Gaussian distribution a good fit for inter-key pauses and mapped specific pauses to

Donia Malekian, James Bailey, Gregor Kennedy, Paula de Barba and Sadia Nawaz "Characterising Students' Writing Processes Using Temporal Keystroke Analysis" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 354 - 359

planning process in case they were identified to be long enough. In other work by [1], a mixture of lognormal distribution was used to describe pause pattern in students' inter-key and intra-word pauses. The parameters of the distribution were found to be correlated with writing score. Finally, [9] estimated the distribution of the inter-key and intra-word pause durations for each student and found the best fit to be a heavy-tailed probability distribution called a stable distribution. Because of nearly identical estimates for intra-word and inter-key pauses, they focused on only analyzing intra-word pauses. They found the estimated parameters for each student to be a strong predictor of final score utilizing a linear regression model.

Although these studies provide informative (predictive) models characterizing students' writing process, the effect of isolated phases of writing process have not been evaluated in these models. In addition, even though the use of simple models of regression and correlation analysis makes the interpretation of results easier, the use of more complex models may capture further information about the interrelationships between the extracted characteristics.

Another direction of research focused on using keystroke logs to more comprehensively characterize the phases comprising the writing process [9, 18]. In a study by [2] on modelling students' writing process, some measures were defined to model pauses, bursts and revisions. A burst is defined as the sequence of fast text production and can be identified based on the production of text between two pauses [2]. They suggest that long pauses may reflect planning, as the writers are more likely to have short but well-formed bursts of writing afterward.

Overall, extracted characteristics from keystroke logs in terms of burst, revision summaries and the pattern of pauses, provide important information regarding the underlying writing process. Association of each extracted characteristic with writing quality has been mainly considered as the metric for evaluating the usefulness of the feature [9, 18]. A major challenge is defining meaningful summaries from the writing keystrokes that represent a specific phase of students' writing process as much as possible. To address this problem, we use an innovative writing technology that more explicitly discriminates between the planning and writing phases, by providing separate writing sections to students [17].

Additionally, it is important to know not only which writing phases are relevant to successful writers, but when and in what order they engage with these phases. An approach to temporal data processing has been the aggregation of data in multiple consecutive episodes, so all participants have a similar number of observations [3]. They suggested that the relation between specific aspects of the process with writing quality varies as students' progress in their writing. For instance, the correlation of structuring activities and writing quality is highest at the start of the writing and is lower toward the end [3]. The importance of the temporal analysis of the writing process has been emphasized by several studies [16], however the data representation mostly relies on think aloud procedures and offline measurements that have been criticized as being inaccurate representation of the underlying writing process [16].

Although the importance of taking the moment(s) at which specific aspects of the writing process occur has been emphasized, this is not a dominant view in keystroke logging analysis.

2.3 Current Study

Our first aim is to characterize students' writing processes in terms of a set of features demonstrating the isolated phases. For this purpose, we focus on students' keystrokes characteristics while taking notes, writing the main body of the essay, and organizing

references (each separately). Utilizing a machine learning model, we examine whether section specific characteristics are more predictive of writing quality compared to the characteristics extracted from the overall keystrokes. We also consider adding more features that estimate burst and revision behavior, as well as features representing the extent to which specific aspects of writing process were used during the writing. To evaluate how influential each feature is for each student's writing quality, we adopt a method called SHAP [13] that describes the importance of each feature on the model's prediction for each student. The second aim of the paper is to provide a temporal analysis which helps us to understand whether the importance of features varies over time or remains stable. We address this problem by breaking down students' keystrokes into several writing episodes and comparing the influence of each feature on writing quality across them.

Overall, in this study the following research questions are explored:

1. Do models that characterize the overall writing process miss informative features associating with particular phases of writing? Can we define new characteristics (features) from students' keystrokes to improve these models?
2. How predictive of writing quality are the extracted features at different times? Do we see evidence that the importance of features varies with time?

Our results highlight that characterizing students' keystrokes separately while writing, taking notes and organizing references is more predictive of their writing quality. Additionally, based on our findings, the importance of several features on writing quality changes over time. Investigation of the influential features for individual students clarified the non-linear relationship between some features and writing quality that confirms there exists considerable overlap and interaction between writing phases [4].

3. METHODS

3.1 Participants and Context

The study involves 107 students from the University of Melbourne who enrolled in a business undergraduate course. Students were asked to use a specific online word processing software called Cadmus to write a 1000-word essay as a part of their course, worth 10% of their final mark. Students had to choose between two topics and had 19 days to complete the essay. The performance was marked by teaching staff using a score between 0 to 100.

Cadmus has similar features to other word processing software tools such as body section for writing (body section), editing, highlighting, and additional features such as dedicated sections to take notes (note taking section), and to organize the reference materials (reference section) as well as a single paste restriction of 90 words. Cadmus records every keystroke in each section via the keyboard while students work on their assignment. A more detailed description of this software can be found in [17].

3.2 Data Processing

We next describe the procedure undertaken to characterize students' writing processes by engineering a set of features from keystroke logs. We also processed two concepts of *writing quality* and *writing episode* to assist on answering the research questions.

(A preliminary analysis revealed 4 students had less than 600 words in their essay. They were removed from further analysis.)

3.2.1 Pauses

In this study our focus is on inter-key pauses (the duration between successive keystrokes) that are more likely to be associated with

such processes as deliberation, text planning, reviewing the written text [9]. As [9] suggested, there is a tendency for inter-key pause durations to follow a stable distribution. They fitted this distribution to pause duration data to obtain an informative estimation of the related parameters for each student. We follow a similar procedure as [9]; however, we summarize pauses in each writing section of our dataset separately. This section-specific summarisation could reveal more explicit information regarding which processes were more likely to be engaged during the pause.

We aim to represent students' writing process while they are working on their essay, thus we decided to ignore the pauses more than 2 hours that meant the student had left the session.

In our dataset, the exploration of the distribution of pause durations for each student in each writing section reveals that there is a tendency for pause duration in each section to follow a heavy tail distribution, that means the majority of the pauses are short but there exist a few long pauses. Believing a stable distribution to be a plausible hypothesis, we fitted this distribution to each student's pause data to obtain an estimate of the related parameters in each section. This distribution needs four parameters (α , β , γ , δ) for the complete description.

- The parameter alpha $\alpha \in (0, 2]$, called the tail index. This parameter gives information about the height of the tails.
- The parameter beta $\beta \in [-1, 1]$, called the skewness parameter. The distribution is symmetric if $\beta = 0$. It is skewed to the right if $\beta > 0$, and to the left if $\beta < 0$.
- The parameter delta $\delta \in \mathbb{R}$, is equal to median. Depending on how heavy the tail is, some extreme part of the data may need to be discarded to have a good estimate of this value.
- The parameter gamma $\gamma > 0$, called scale parameter is a measure of dispersion.

Parameters alpha and beta determine the distribution's shape, while parameters gamma and delta define the scale and location of it. For each student, in each section of our dataset we obtain these four estimated parameters. We also estimate these parameters for the overall keystrokes of each student (irrespective of the specific section) as suggested by [9] and consider them as a baseline for the purpose of evaluation.

3.2.2 Bursts

Burst summaries (i.e. mean length of the bursts) can reveal students' fluency in the transcribing phase of the writing process [18]. In keeping with the majority of the literature [14], we identify bursts by breaking up keystrokes at every pause that have longer than 2 seconds of inactivity. We apply this procedure in the body section of our dataset, where students write the main part of their essay. Considering the bursts in which at least one word is typed, we summarize burst length by two features based on the number of words in a burst: The *mean* and the *standard deviation of burst length* for each student. Additionally, we summarize burst duration by two features of *mean* and *standard deviation of burst duration*.

3.2.3 Revision

In this step, our aim is to isolate the revision phase of the writing process from the transcribing phase. Authors of [5] associated single backspaces to spelling correction which reflect self-monitoring, and multiple backspaces to editing in which longer revision occurred. Similarly, we summarize revision at small and large scale with a slight change in the definition; we identify revisions based on the number of word deletions in a writing burst rather than in isolation. We label a burst with single deletion as

small, whereas bursts with multiple deletion as large-scale revision. Two features were extracted to provide measurements related to the revision phase of writing process: The *frequency of both small scale and large-scale revision bursts*.

3.2.4 Time percentage on each writing aspect

To summarize the extent of each specific aspect of writing that was used by each student, we introduce a new set of features, including *the percentage of the total writing time* dedicated to: note taking (total time in note taking section), small- and large-scale revisions (bursts of writing with small or large deletion), transcribing (total time of bursts), and reference organization (total time in reference section).

3.2.5 Writing quality

Writing quality corresponds to the students' final grades on the essay [9, 18]. Previous research has found that students' final grade may not be a reliable measure of success, due to variations in grading essay writing by raters [11]. To account for this variability, we map the students' writing quality to two categories - high and low level instead of the exact grade. In our dataset, the distribution of students' grades lies within the range 60 to 95. We adopt the median value as a threshold for this mapping which is 80. Based on this value we have 40 and 67 students having high quality and low quality writing respectively.

3.2.6 Writing episode definition

One approach to temporal data processing is the analysis of data in multiple episodes to ensure all participants have a similar number of observations [3]. In our study, students were asked to write a 1000-word essay, which provides a good criterion for defining the fixed observations. We define the episodes based on the keystrokes used to complete the fixed number of words in the essay. This way, we have meaningful episodes recording a specific draft of writing.

We split students' writing data into n writing episodes, $\{E_1 + E_2 + \dots + E_n\}$, each of which records students' keystrokes used from the start of writing to the completion of $n*k$ words of the essay. We define 5 writing episodes, each of which involves all the keystrokes from the start of writing to the completion of $n*200$ words. There is no theory for defining the number of episodes and the results may differ based on the choice of this number.

4. Data Analysis

We conducted two sets of analyses: one for each research question.

4.1.1 Research Question 1.

To answer whether models that characterize the overall writing process miss informative features associated with certain phases of writing, we compare the performance of a machine learning model trained on the pause related features extracted from overall keystrokes (*baseline* feature set) to the performance of a model trained on pause features of each writing section separately (*section-specific* feature set). Work in [9] also identified the *total time on task*, along with the pause related features as a strong predictor of writing quality. Thus, we include this feature in the *baseline* and *section-specific* feature sets. Our evaluation is based on the prediction performance of writing quality.

Then, we examine whether we can define new characteristics from students' keystrokes to improve our model. For this purpose, we evaluate our model by adding further features of burst and revision summaries (explained in section 3.2.2 and 3.2.3), as well as the features representing the extent to which specific aspects of the writing process were used (section 3.2.4). We refer to them as *combination* feature set. We utilised XGboost classifier [6] for the

prediction models. Even though this classifier generally provides a good prediction power compared to simple models of regression, understanding what the contribution of each feature were seems to be hard due to the complexity of the model. To evaluate and derive the influence of each feature on writing quality, we use SHAP (SHapley Additive exPlanations) algorithm which can be used to explain the output of any machine learning model [13]. In this algorithm the contribution of a feature is calculated by comparing what a model predicts with and without that feature. Every individual is assigned a SHAP value for each feature that determines the feature's contribution for a change in the model's prediction.

4.1.2 Research Question 2.

To examine how predictive of writing quality are the extracted features at different times, and how their contribution may vary, we broke down students' keystrokes into n episodes from each of which the predictive features (*combination* feature set) were extracted. Then for each episode the predictive power of the features on writing quality was evaluated using the XGBoost model. To identify and compare the contributing features to the models' prediction in each episode, SHAP algorithm was utilised.

5. RESULTS

5.1 Results for Research Question 1

First, we report and compare the prediction power of the introduced feature sets on writing quality. Then we derive and discuss the contribution of each feature on prediction.

5.1.1 Examining the prediction power of feature sets on writing quality

For each set of features a model was trained using leave one out cross validation (with 5-fold nested cross-validation for parameter optimization). The performance of each model on the prediction of writing quality is reported in Table 1 based on the metrics of accuracy and the area under the ROC curve (AUC) [12]. The accuracy and AUC were slightly higher for the *section-specific* feature set compared to the *baseline* set. This could indicate that characterizing the overall process irrespective of the isolated phases may miss specific moments where the features associated to certain writing phase become more important. Adding burst and revision summaries, as well as the time dedication features (*combination* feature set), to the model, improved the performance of the prediction significantly. The *combination* feature set obtained the highest prediction power implying that the introduced features were a better representation of the students' writing quality.

Table 1: Prediction power of each feature set on writing quality based on accuracy and AUC

Features set	Accuracy	AUC
Baseline	70.09	70.63
Section-specific	71.03	71.75
Combination	81.31	82.72

5.1.2 Examining the contribution of features on prediction

The next step was to evaluate the influence of each feature on predictions. For this purpose, we built an XGBoost model on the *combination* feature set (using 5-fold cross validation for parameter optimization). The model was then passed to the SHAP algorithm to explain the influence of each of features on the model's prediction for each student. Since we get individualized explanations of every feature for every student (based on the SHAP values), we can plot the distribution of the importance of each

Figure 1: SHAP values for each feature indicating the influence of that feature on writing quality of each student. TT refers to the total time on writing. R, B, N before each feature name refer to Reference, Body and Note sections respectively. α , β , δ , γ refers to pause parameters. TSRev, TLRev refers to the total time on large- and small- scale revisions respectively. FSRev, FLRev refers to the frequency of small- and large- scale revisions. T refers to the total time on specific section. MBrstT, SBrstT are mean and standard deviation of burst time. MBrstL, SBrstL refer to mean and standard deviation of burst length.

feature on the model's prediction, as is presented in Figure 1. The features are sorted by the mean of absolute SHAP values over all students to gain a global insight into the most influential features across all students. We observe the most influential features (globally) were total time on task (TT), frequency of small revisions (B-FSRev), and estimated gamma parameter from pauses in body section (B-P γ) respectively, while some of the pause parameters estimated in the note taking and reference sections (i.e. N-P α , R-P β) had the lowest contribution. For convenience of viewing, only the top-20 features that were globally influential are presented in the figure. In this figure, each row corresponds to a feature and every student has one dot on each row. The x position of the dot is the impact of that feature on the model's prediction for the student (SHAP value), and the color represents the value of that feature for the student (red high, blue low). This reveal, for example, that a high percentage of time on the reference section (R-T) increases the chance of having high quality writing for a subset of students (red dots in the R-T row, and on the right side of the plot).

Below is our interpretation of some of the features detected as important by the prediction model. It is worth mentioning that this interpretation is intended for high-level model interpretation, and the model's decision making was more complex and took the interaction between features into account.

Total time on task (TT) was found to be the strongest predictor of writing quality. A subset of students (red dots on the related row of figure) who spent a lot more time than others on the essay are more likely to produce a high-quality writing. This supports previous research [9] and could be an indication of student's motivation in completing the writing task [10]. However, there are also students with lower time spent on task, but a higher chance of producing high-quality writing (blue dots on the right side of the plot in the

Figure 2: Visualization of the global importance of each feature on the prediction in each writing episode based on the SHAP values. Darker colors indicate higher contribution of that feature on prediction in that episode.

related row). This could indicate other features are impacting the contribution of this feature.

The coloring of the second most important predictor - the percentage of time on small revision ($B-FSRev$) shows us how a higher frequency of small revision means a higher the chance of producing high quality writing for most students. It could imply that the writing quality improves if revisions are performed more frequently. This is in agreement with previous research [15] suggesting that good writers stop their writing more often to perform revision and to correct their spelling and grammatical errors as they write compared to weak writers.

The estimated gamma and alpha parameters from pauses inside the body section ($B-P\gamma$, $B-P\delta$) shows a (negative, positive) association with the chance of producing a high-quality writing for most of the students. Together these parameters mean lower variation of pause durations without having very large pauses. This could be an indication of steadiness and fluency in writing and its direct relation with writing quality which is in agreement with previous research [9]. Percentage of time on reference section ($R-T$) also shows a positive effect on writing quality for several students. Again, we observe that this argument does not hold true for several students.

The higher percentage of time on transcribing ($B-T$) increase the chance of having high-quality writing. One alternative justification could be found in a study by [8]. They found that writers who spend most time on other aspects of writing such as planning tend to dislike writing and this may lessen the text quality.

Estimated delta and gamma parameters from pauses in the note taking section ($N-P\delta$, $N-P\gamma$) shows a (positive, negative) association with the chance of producing a high-quality writing for most students. Together these parameters mean more large pauses and lower variation in pause duration. This means that steadily taking large pauses while taking notes leads to a higher chance of high-quality writing. Based on a work by [2], large pauses may reflect planning process. Since this pattern is observed in the note taking section of our dataset, we could more certainly connect these steady long pauses to thinking periods on planning.

Even though there are several features such as percentage of time on small revision ($B-TSRev$), mean burst length (B_MBrsL), estimated gamma from reference and body section ($R-P\delta$, $B-P\delta$), that are detected as influential, we cannot observe their clear linear association with writing quality. For a subset of students, the higher value is associated with higher quality and for others it is the opposite. Again, this indicates that the importance of these features is impacted by other features.

5.2 Results for Research Question 2

In this section we answer the second research question in two steps.

5.2.1 Examining the predictive power of features on writing quality over time

Using the XGBoost classification algorithm, we examined the predictive power of the extracted feature in our study (*combination*

feature set) on writing quality at each writing episode. We report our result using the metrics of accuracy and area under the ROC curve (AUC), based on leave one out cross-validation (with 5-fold hyper parameter optimisation). The outcome is shown in Table 2 demonstrating a high and, in some episodes, moderate success rate in predicting students' writing quality (better than random chance).

Table 2: Prediction power of extracted features in each writing episode based on the accuracy and AUC

Episode#	Accuracy	AUC
1	69.16	70.26
2	67.29	67.12
3	69.16	66.01
4	79.43	79.22
5	81.31	82.72

5.2.2 Examining the contribution of features on prediction over writing episodes

Our next step was to examine the contribution of each feature on the prediction of writing quality at each writing episode and examine whether the contribution varied. For this purpose, an XGBoost model was trained based on the *combination* feature set in each episode (using 5-fold cross validation for parameter optimization). Each model was then passed to the SHAP algorithm to explain the importance of each of feature on the prediction. The result is reported in Figure 2, in which the global contribution of each feature in each writing episode is visualized based on the mean of absolute SHAP values for that feature over all students.

A darker color indicates a higher contribution of that feature on the prediction model in that episode. We see the contribution of features on writing quality are quite different across the writing episodes. Although the importance of total time on task (TT) is relatively stable over all the episodes, the importance of the note taking related features such as percentage of time on note taking section ($N-T$), and estimated pause parameters ($N-P\delta$, $N-P\gamma$) were found to be more influential in the 2nd writing episode. The patterns of pauses in the reference section (i.e. percentage of time on the reference section ($R-T$), as well as the estimated gamma and delta parameters ($R-P\gamma$, $R-P\delta$) also show stronger influence on the prediction of writing quality at the beginning of writing.

Our temporal analysis reveals that the importance of writing behaviour on writing quality may change over time. Thus, characterizing students' writing process irrespective of time may hide the effect of meaningful and predictive writing behaviors. Moreover, this analysis could be used to predict students writing quality over time and act as a filter for early targeting of students with different writing qualities opening up feedback opportunities.

6. DISCUSSION

This study was based on a fully online web authoring tool called Cadmus. The availability of separate sections for body text, note taking and referencing allowed us to separately extract the

keystroke logs of different sections. From these logs we were able to engineer multiple sets of features capturing different aspects of students' writing processes ranging from patterns of pauses, burst and revision summaries as well as the time dedicated to specific aspects of the writing process. We compared the performance of a model trained on the pause pattern related features extracted from overall keystrokes (*baseline*), to the performance of a model trained on pause pattern related features of each writing section separately. The section-specific model performed slightly better. This indicates that the baseline model may miss or "overlook" on specific moments where the features associated with certain writing phases become more important. The performance of the section-specific model was further improved by adding more features including burst and revision summaries and percentage of time on specific activities.

The feature importance of the resultant model is visualized for every student showing how specific behaviour that have positive effect on writing quality for one student may have negative effect for another because of the impact of other features. This is consistent with a theory of writing which suggests there exists considerable interaction and overlap between writing phases [4]. This also emphasises the necessity of using models that capture the interrelationship between features rather than simple correlation and regression analysis.

The current study also examined whether the influence of extracted features on writing quality varies during specific moments of writing. Based on our results, the influence of several features varied across writing episodes indicating the importance of taking the temporal aspects of writing process into account. Through this study, we hope to develop a better understanding of students' writing process in authentic educational settings.

More detailed results, discussions, and additional figures that could not be included in this version of the paper for the reason of space, is available in the longer version of the paper on this [link](#).

6.1 Limitations and Future Work

The first limitation of this study is the generalizability of the interpretations regarding the influential features. This study was based on the essay writing of undergraduate students with diverse writing and language backgrounds. The influential features might differ for data from a more diverse set of students and across variations in topic, genre and prompts. The next limitation arises from considering all the activities in the note taking and reference sections to be associated with the related phase of writing. This association is irrespective of the actual written text. For the next study we aim to consider the actual text entered in each section. This may help to distinguish between weak and strong planning behaviour and the related impact on writing quality.

ABSTRACT

Educational systems use models of student skill to inform decision-making processes. Defining such models manually is challenging due to the large number of relevant factors. We propose learning multidimensional representations (embeddings) from student activity data – these are fixed-length real vectors with three desirable characteristics: co-location of similar students and items in a vector space; magnitude increases with skill, and that absence of a skill can be represented. Based on the Multicomponent Latent Trait Model, we use a neural network with complementary trainable weights to learn these embeddings by backpropagation. We evaluate using synthetic student activity data that provides a ground-truth of student skills in order to understand the impact of number of students, question items and knowledge components in the domain. We find that our data-mined parameter values can recreate the synthetic datasets up to the accuracy of the model that generated them, for domains with up to 10 simultaneously active knowledge components, which can be effectively mined using relatively small quantities of data (1000 students, 100 items). We describe a procedure to estimate the number of components in a domain, and propose a component-masking logic mechanism that improves performance on high-dimensional datasets.

Keywords

knowledge representation, skills embeddings, multicomponent latent trait model

1. INTRODUCTION

Intelligent tutoring systems (ITS) are required to make decisions about which tasks to present to which students. Thus they should be equipped with objective, accurate models of student skillsets, to inform these choices. Student activity logs are a source of information for such models, which could be built by hand-crafted feature extraction, or using data mining methods. We explore the latter, using machine-learning of fixed-width multidimensional representations.

Russell Moore, Andrew Caines, Mark Elliott, Ahmed Zaidi, Andrew Rice and Paula Buttery "Skills Embeddings: a Neural Approach to Multicomponent Representations of Students and Tasks" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 360 - 365

tations. We call these SKILLS EMBEDDINGS, after *word embeddings* – vector representations of words and language constructs that have allowed dramatic advances in the natural language processing field [6, 8].

With word embeddings, semantically similar words are positioned near each other in a latent vector space: *e.g.* ‘boat’ should be nearer to ‘car’ than ‘politics’, based on natural language data. We transfer the vector space idea to skills. For the ITS scenario, we seek specific desirable traits:

- Skills embeddings are **co-proximal** in the vector space if they represent entities comprising similar skills.
- Embedding **magnitude** grows with skill – specifically, a higher skill level should entail a larger value within the embedding. This lets us track skill gain intuitively.
- It should be possible to represent the special case where a skill is absent. We will refer to this characteristic as **skill masking**.

We would also ideally like to be able to **detect dimensionality**: the number and dependency structure of skills within the domain should not need to be specified in advance.

In this work, we propose an artificial neural network – based on the Multicomponent Latent Trait Model [12] – to learn skills embeddings. We train it using synthetic student activity datasets, with a varying number of skills in the domain. We show that the embeddings exhibit our three desired characteristics, and present a procedure to cater to the fourth.

2. BACKGROUND

Our work relies on some core principles about the nature of knowledge domains, the way that student ability and item difficulty interact, and the idea that knowledge acquisition can be traced in student activity logs [5].

2.1 Knowledge components

For any given educational domain, such as physics, mathematics or language learning, we can break domain-specific knowledge down into atomistic units known as KNOWLEDGE COMPONENTS (KCs), as described by Koedinger *et al.* [4]. We treat these as synonymous with ‘skill’ where the skill is irreducible – if skill C comprises irreducible subskills A and B, we do not represent C, but treat co-occurrence of A and B as the pattern for C. We think of a subject domain as a

set K of KCs to be acquired. In our datasets, domain size $|K| \in [1, 100]$.

2.2 Rasch model

The Rasch item response model [11] is a well-known formulation for the success probability of student s attempting item (question) i , derived by transforming the difference between student ability θ_s and item difficulty β_i through a sigmoid function. That is, the probability of success is given by:

$$Pr(X_{si} = 1 \mid \theta_s, \beta_i) = \sigma(\theta_s, \beta_i) \quad (1)$$

where σ is the standard logistic sigmoid function:

$$\sigma(\theta_s, \beta_i) = \frac{1}{1 + \exp(-(\theta_s - \beta_i))} \quad (2)$$

Note that an evenly-matched student-item pair has $\theta = \beta$ and a pass-rate of 0.5. The Rasch model assumes a single dimension of proficiency and embodies *invariant comparison* – this means the student parameter θ can be eliminated algebraically during estimation of the item parameters β , and vice versa [9, 14]. This principle allows Rasch items (and by extension our embeddings) to stand alone as objective representations, independent of the conditions in which they were measured.

2.3 Multicomponent Latent Trait Model

The Rasch model can be extended to the MULTICOMPONENT LATENT TRAIT MODEL (MLTM) of Whitely [12]. Here, the scalars θ and β are replaced by vectors, and the result is a product of sigmoids. The formulation is as follows:

$$Pr(X_{si} = 1 \mid \theta_s, \beta_i) = \prod_{k \in \text{skills}(i)} \sigma(\theta_{sk}, \beta_{ik}) \quad (3)$$

Hence the act of student s successfully passing item i is modelled as the conjunction of successes at each of the item’s problem-solving steps (denoted k). The probability is given by the product of the probabilities of completing the steps and each step behaves as a Rasch model whose parameters are the corresponding elements of θ_s and β_i .

2.4 Item calibration

Traditionally, item calibration with Rasch-type models is carried out using the Birnbaum iteration [2]. However, the Birnbaum algorithm is one-dimensional and to the best of our knowledge has not been extended to multiple dimensions. Moreover, the Rasch approach does not readily allow for the absence of skills: parameters would have to be set to $-\infty$, which is impractical for data mining, particularly in cases where the skill is absent both from a question and student’s representations¹

2.5 Q-Matrix

The Q-MATRIX [10, 1] is a binary- or probability-valued matrix that describes which skills are required for particular tasks. This has been used previously, for instance, in the Linear Logic Test Model [13]. Each column of \mathbf{Q} represents a task/item i , and each row a component $k \in K$.

¹Even assuming infinite arithmetic is allowable, if θ and β are both $-\infty$ then $(\theta - \beta) = 0$ and the probability of success is calculated as 0.5; in fact, for an unrequired skill, it should always be 1, since an unrequired step is always ‘passed’.

Figure 1: Neural network architecture

The (binary) Q-matrix for a curriculum of items is as follows:

$$q_{ik} = \begin{cases} 1 & \text{if } k \in \text{skills}(i), \\ 0 & \text{else;} \end{cases} \quad (4)$$

The Q-matrix for students is similar, with element q_{sk} representing the ability of student s at skill k .

3. DATA

Our datasets follow a *summative* assessment scenario: the item bank is a static test, to be attempted by many students. Each student attempts all items only once. Each response is dichotomous: either right ($X=1$) or wrong ($X=0$).

Student activity data is synthesised using a statistical model whose probability mass function (pmf) is just equation (3). The response x_{si} (of student s on item i) is determined by ground-truth values of the MLTM parameters, θ_s^* and β_i^* . These are the targets we hope to recover from the dichotomous outcome data: we want our embeddings to converge on these values.

The elements of θ_s^* and β_i^* themselves are generated uniformly randomly for each student and item – their minimum and maximum values are chosen by an earlier randomised search process, that looks for suitable bounds to generate a balanced dataset given a specific dimensionality $|K|$.

We generated datasets with dimensionalities $|K| \in \{1, 2, 5, 10, 100\}$. We also created datasets where only a subset of components are active – for these datasets, the active components are chosen at random. We use $|I|=100$ items and $|S|=1000$ students.

4. IMPLEMENTATION

In this section we describe the neural network, including its design features, software used, and training approach.

4.1 Neural network architecture

The neural network in this work is a binary classifier. In a normal supervised learning task, a classifier takes an input set of features $\Phi(x)$ and class label C and learns the probability that a datapoint x is in a given class: $Pr(x \in C \mid \Phi(x))$.

In the embedding generation task there is no feature mapping Φ . Instead we have datapoints of form $(s, i, pass \in \{T, F\})$, describing whether student s passed item i . Inputs to the neural network are s and i , and class label $pass$.

The ‘features’ themselves are learned internally, with two distinct sets of trainable weights. One set of weights ($\Theta \in \mathbb{R}^{|S| \times |K|}$) represents the students, the other ($B \in \mathbb{R}^{|I| \times |K|}$) the items. Whenever s occurs in a datapoint, the weights for s (synonymous with θ_s) are selected from the table, and the same happens for β_i when i occurs.

The weights are fed into a locally connected layer that represents the components of the MLTM. Each unit in the layer applies a sigmoid function to generate a per-component probability. The component probabilities are then multiplied to get the overall output probability. This is scored against the true $pass$ value using a loss function, and the error is backpropagated to the weights tables. The weights are re-used whenever s or i appear in a datapoint, so they are forced towards values which best fit all observations. The trained rows of weights serve as our fixed-width embeddings.
